NEW ELEMENTS OF OPERATIVE SURGERY:

BY

ALF. A. L. M. VELPEAU,

Professor of Surgical Clinique of the Faculty of Medicine of Paris, Surgeon of the Hospital of La Charité,
Member of the Royal Academy of Medicine, of the Institute, &c.

CAREFULLY REVISED, ENTIRELY REMODELLED, AND AUGMENTED WITH

A TREATISE ON MINOR SURGERY.

ILLUSTRATED BY

OVER 200 ENGRAVINGS, INCORPORATED WITH THE TEXT:

ACCOMPANIED WITH

AN ATLAS IN QUARTO OF TWENTY-TWO PLATES,

REPRESENTING THE PRINCIPAL OPERATIVE PROCESSES, SURGICAL INSTRUMENTS, &c.

FIRST AMERICAN, FROM THE LAST PARIS EDITION.

TRANSLATED BY

P. S. TOWNSEND, M.D.

Late Physician to the Seamen's Retreat, Staten Island, New York.

AUGMENTED BY THE ADDITION OF

SEVERAL HUNDRED PAGES OF ENTIRELY NEW MATTER,

COMPRISING ALL THE LATEST IMPROVEMENTS AND DISCOVERIES IN SURGERY,
IN AMERICA AND EUROPE, UP TO THE PRESENT TIME.

UNDER THE SUPERVISION OF, AND WITH NOTES AND OBSERVATIONS BY

VALENTINE MOTT, M.D.

Professor of the Operations of Surgery with Surgical and Pathological Anatomy, in the University of
New York; Foreign Associate of the Académie Royale de Médecine of Paris,
of that of Berlin, Brussels, Athens, &c.

TO THE THIRD AND LAST VOLUME OF THIS WORK.

BY P. S. TOWNSEND, M.D.

---

IF it were possible that any portion of these volumes could be considered more valuable to students and to practitioners than the rest, we should say, apart from the great capital operations on aneurisms, amputations, exsections, &c., in the 2d volume, and the rudimental subjects of minor surgery and the new operations embraced in the 1st volume,—that the *special* operations on all the varied regions of the human body, contained in this 3d and last volume, especially in relation to the important subjects of Hernia and Tumors, and those most difficult manipulations exacted in the minute and delicate surgery of the face, neck, and all the different vital organs and passages considered separately, together with the accompanying beautiful quarto atlas of nearly 200 figures of surgical instruments and processes, would unquestionably bear the palm of precedence for direct practical utility.

The whole, as will be perceived, have been treated of with the habitual felicitous manner of M. Velpeau, both in regard to the perspicuity of the style of the author, and his intimate practical familiarity with the operations themselves. But for having been already somewhat accustomed, however, to his manner of describing surgical processes, we should have despaired of rendering some of the more intricate of these operations intelligible in our own language.

We trust we have succeeded, at least we count with some degree of security on not having committed in any place, any sensible deviation from the path traced out for us, while endeavoring to adhere as closely as possible to the meaning of the original, and at the same time to convey the ideas of the author into our own idiom, in a manner, we hope, not entirely wanting either in spirit or perspicuity.

We are gratified in being enabled to state from a recent letter of M. Velpeau, that the work, so far as it had progressed, had met with his entire approbation; so much so, that he hesitates to our enquiry of his intention to publish a second French edition, by saying that he should meditate upon this present work, in order to satisfy himself first, that the necessity of such a task had not been fully anticipated by our labors.

The text of this present volume, we may furthermore remark, is so ample and searching in its details, and so perfectly *au courant* to the present condition of surgery, in respect to the subject-matters therein embraced, that any attempt almost on our part, to superadd any thing new to what M. Velpeau himself has said, has been almost entirely superseded. Nevertheless, it will be perceived that we have deemed it advisable to incorporate some 100 pages of new matter in various places, among which the animated discussion still in progress, on the diagnosis of *Fibrous and Cancerous Tumors*, and the important, though brief remarks of Dr. Mott on his eminently successful mode of treating the distressing affection of *Immobility of the Lower Jaw*, will, we are sure, be found of some interest to the profession.

While touching on this matter, we may remark, that in a case of this kind, and as an auxiliary to the screw-lever of Dr. Mott, the right *masseter* muscle was TOTALLY divided, and the *left* partially so, as early as the year 1840, by James R. Wood, M. D. of this city. Complete success, however, did not reward the bold expedient of this skilful young surgeon, which, however, might possibly have been obtained if it had occurred to him to have adopted the ingenious resource of his preceptor, Dr. Mott, by severing also the pterygoid muscles.

We are somewhat strengthened in this opinion by what happened in the case of M. DIEULAFOY, of Toulouse, who also after all the discussion which has occupied our pages, (see Vols. I. and II., Drs. Schmidt and Carnochan,) on the claims of priority for the *total* division of the masseter, appears to have been the *first* surgeon, who *first* actually achieved this triumph, as well as a complete cure in the case in question, but *not* until after the subsequent partial division of the *pterygoid* muscles.

M. Dieulafoy, according to the *Journal de Méd. et de Chirurg. Prat.*, of August, 1839, divided the year before (1838) by puncture in the cheek externally, and then by the subcutaneous method the entire *right masseter* in a soldier aged 29, at the Hotel Dieu, Saint Jacques (Toulouse,) in whom the muscle on this side had become permanently contracted, and to such degree in consequence of scurvy, while with the French army in Africa, as to effect a rigid closure of the jaw. The cure was, however, not completed until the surgeon, after the cicatrization of the wound, had divided also the *anterior fibres of the pterygoid muscles*, which formed a bridle behind the last molar teeth. (See also *American Journal of the Med. Sciences*, Vol. XXVI., Philadelphia, 1839, p. 218.)

While on the subject of the adjustment of disputed claims,—the preceding one having now we presume been put forever at rest,—we will remark, that we have in our notes to Vol I., taken occasion to bestow some laudation upon Dr. Mott, as the first person, who upon his last return from Europe, took an early opportunity to establish at the University of this city, and upon a secure basis, the valuable course of public instruction and gratuitous surgical services to the poor, known for the first time in our country, but for several years since in Europe as a *Medical and Surgical Clinique*.

Dr. March, an esteemed Professor in the Medical College of Albany, claims priority on this subject—by a year or two in advance of Dr. Mott. We are ready to concede to him all the praise he is thereby entitled to. But we will observe, that so far as public attendance and surgical operations, and medical prescriptions for the out-door poor soliciting advice at hospitals, dispensaries, &c., goes, the matter of *Cliniques* (applied in an inverse sense to the truth so far as the etiology of the word or *bed-side* practice is considered,) is quite an old affair all over the world, having been in common vogue for a century, or for half a century at least.

It is a source of infinite satisfaction both to Dr. Mott and myself, to have an opportunity at this late hour, of rescuing another and more important surgical claim from oblivion, by the accidental acquaintance we made during the past summer with the venerable Walter Brashear, M. D., for many years an eminent planter of Attakapas, Louisiana, and a senator of that state.

To our countryman, Dr. Brashear, who was a pupil of the eminent Dr. Ridgeley, of the continental army of the revolutionary war, and also a student at the University of Philadelphia, under Dr. Rush and other famous men of that day, are we indebted as is now ascertained, for the *first* operation, or amputation of the thigh at the hip joint or *coxo-femoral articulation* ever performed in America, and which was followed with complete success. This occurred as early as the year 1806, *only three years* after the illustrious Larrey had revived and perfected this operation in the campaigns of Napoleon. (See text of M. Velpeau on this subject, p. 637. &c. in Vol. II. of this work.)

With that self-neglect of one's own rights, that is ever a prominent characteristic of the diffidence of men of genius, and from his having early in life withdrawn from active practice, Dr. Brashear had never published this case. Dr. Mott therefore, as is seen in his case of coxo-femoral disarticulation in Vol. II. of this work, had hitherto supposed that he was the surgeon who in this country had first performed this important operation. With a magnanimity which ever belongs to him, and which we trust will serve as an emphatic lesson to those who in their malignity would rob and calumniate both the dead and the living, Dr. Mott cheerfully abstracts the plume from his own honored brows, that can spare many and much more like this, and affixes it upon the name of the gentleman to whom it rightly belongs.

As it may doubtless become the theme of future discussion, we take the opportunity of placing here upon the record, a too-brief account of the achievement of Dr. Brashear as communicated in his own words, in a letter we have had the honor to receive from that venerable surgeon.

*Philadelphia, August 13th, 1846.*

MY DEAR SIR,

In conformity to promise, I now give you a brief statement of the operation which I performed in Bardstown, Kentucky, in August, 1806, on the hip joint.

The subject was a boy seventeen years of age. Without assigning the causes which led to the necessity of the operation, the same was, after consultation with Drs. Harrison and Goodlet, conducted in manner following:—first premising, that in absence of any knowledge of an established mode for this operation, a common-sense reasoning as to its safety and facility alone dictated the manner of performing it. Therefore an operation of the thigh in the ordinary manner was determined on, as remote from the hip joint as circumstances might justify, (in this case about mid-thigh.) The amputation was performed, and the arteries secured.

The next step was to make an incision to and from the lower end of the bone externally over the great trochanter to the head of the bone and upper part of the socket. The dissection of the bone from the surrounding muscles, was simple and safe by keeping the edge of the knife resting against the bone. The bone being disengaged from its integuments at its lower extremity, was then turned out at a right angle from the body, so as to give every facility in the operation, to separate the capsular ligament and remove the head from its socket. After the operation, nothing more than ordinary dressings were used, and in the course of a short time the patient removed to St. Louis, where he was living within a few years past.

I am, very respectfully,

WALTER BRASHEAR.

*Dr. P. S. Townsend.*

It may be proper to state from the verbal communications we have had with Dr. Brashear, that the injury which led to the operation in question was a fracture of the thigh, complicated with much contusion of the parts, and which from bad management or neglect, or both, resulted in the establishment of an extensive and dangerous suppuration in the neighboring tissues and inter-muscular spaces.

To another of our countrymen and a citizen of New York, Prof. John W. Francis, M. D., we would with pleasure have also devoted a larger portion of space in the body of the text than we shall in this preface have an opportunity to do, had not the volume already become augmented to such size as to preclude the possibility of giving the details of all the interesting and important cases of ovarian and other tumors which have occurred in his obstetrical practice, and the principal part of which must be reserved for a second edition.

Professor Velpeau, in his various valuable publications on obstetrical science, has with his usual discrimination adverted to the several affections with which the uterine system is at times invaded, and hence we may account for the omission of his elaborate disquisitions in the present work, on the subject of the several forms of uterine tumors, and the disorders of the ovary. A chapter of some extent might unquestionably be embraced in this work, on this great topic, so closely associated with medical and surgical practice, inasmuch as the services of several of our American practitioners and operators have shed light on the pathology of these disorganizations, and enforced by surgical measures additional means for the alleviation of these morbid conditions. The cases of extirpated diseased ovary by Dr. M'Dowell, of Kentucky, as recorded in the Eclectic Repertory, evince not less the skill than the intrepidity of this bold operator of tumors connected with the uterus. We may search in vain I believe, for any instances of so formidable a bulk as that recorded by Professor Francis in his improved edition of *Denman's Midwifery*. The case fell under the observation of Professor Mott, and the circumstances characterizing the case are given in the work just alluded to with great minuteness. The patient was aged about 32 years: the tumor grew from the fundus of the womb, externally. According to evidence taken at the time of the post-mortem examination, the entire mass of abnormal growth, including several excrescences attached to the tumor itself, weighed one hundred and one pounds. Its fibrous nature was evident. Upon cutting into its substance in different directions, a sac was found in its right portion, out of which issued three quarts of a purulent and most offensive matter. The extent of the abdomen of the patient, before the removal of the tumor measured four feet eight inches and a half. Professor Francis has in the same work given other cases of fleshy tumors of the uterus; and in the

*New York Medical and Physical Journal* other instances of uterine affections with extensive ovarian dropsy.

In conclusion on the subject of *reclamations*, and without deeming it at all necessary to pay the slightest attention to some puerile and insignificant pretensions which have been set forth and vehemently insisted upon in sundry *professed* notices and maudlin criticisms on the two first volumes, we will here barely state, that in a respectful communication transmitted to us from Dr. SAMUEL S. WHITNEY, under date of Dedham, (Mass.,) March 5th, 1846, he claims the honor of having been the first person,—and before Dr. Ruschenberger of the U. S. Navy, to whose communication (see Vol. II. of this work,) he alludes,—in this country at least—who clearly diagnosed a case of *unequivocal* aneurism of the *basilar artery*. Dr. Whitney says (see his case in the Oct. number of the *Philadelphia American Journal of the Medical Sciences*, for 1843,) that this occurred as early as the year 1841, and during the time he was making investigations and collecting facts in regard to *cerebral auscultation*.

Not only has the complete exsection of one half the lower jaw, and various portions of the upper maxillary bone, been long since performed by Dr. Mott and many other surgeons, (see text of Vol. II.,) but also recently the exsection of the *entire upper jaw on both sides*. This was accomplished July 23, 1844, by a surgeon of Germany, Dr. Heifelder, of Erlangen, on a male patient aged 23, for an indurated tumor, occupying the vault of the palate, and which had displaced and elevated the nose, &c. The operator made two incisions, each commencing at the great angle of the eye, and terminating at the commissure of the lips, circumscribing thus together a quadrangular flap, which was reversed upwards on the forehead. Passing Jeffrey's chain-saw through the left speno-maxillary fissure, (*fente*,) he detached the maxillary bone from the zygoma; proceeded in the same manner on the right side, and then separated both bones from the frontal, os unguis and ethmoid by the same saw; separated the vomer and other adhesions with the seissors, and brought down and united the flaps by 27 points of suture. There was no hemorrhage or fever, and the cicatrization was complete in *four days*, and the patient was enabled to swallow with ease. Very little deformity remained, a cleft of 15 lines only being left on the median line of the vault of the palate, (*Walther & Ammon's Journal für Chirurgie*, t. III., f. 4, p. 633, *Arch. Gén. de Paris*, 4e ser., t. IX., November, 1845, pp. 355, 356.)

A new method also of *curing false joints* has been proposed by the illustrious Dieffenbach. In a girl aged 14. (Dr. Hering, *Ueber das Wiedernatürliche Gelenk*; Berlin, 1843, also *Arch. Gén.*, Sept., 1845, p. 100,) with a false articulation in the leg, he at first divided the flexor muscles, which drew the limb into an angular projection, viz., the tendo achillis, flexor longus pollicis pedis, and tibialis anticus, and then by means of two or three very narrow incisions leading down to the bones, applied a small perforating trephine, which he worked drill-fashion, as in lithotomy, till he had made 5 to 8 holes through the morbid osseous parts and their connections. Rapid cicatrization and perfect restoration of the limb followed a short confinement of the limb on a wooden gutter.

The diagnosis of *substernal aneurisms* (see Vol. II.,) is not the only one which has baffled the acumen of the most eminent surgeons now living in the practice of the stethoscope and auscultation. Even the fingers, and most refined sense of touch that can be acquired by long habitude with morbid growths, are frequently found to lead to the most humiliating results as interpreters of the real difficulties that exist. We have in this volume alluded, under the head of *Hematocoele*, to the deductions made in one recent case, by the singular *tremulous* or *oscillating*, or *gelly-like sensation of fluctuation* imparted to the touch, and which after the operation was discovered to have proceeded from the coagulated or clotted condition of the contained sanguineous fluid.

In a recent successful extirpation by Dr. Mott, of a remarkable tumor involving the entire mamma, and of the rapid growth of only 8 months, in a married woman aged about 50, and the uniform ovate or oblong spheroidal shape of which, of the size of a fetal head at full term, was one remarkable feature, we saw a similar scene of embarrassment. Almost every person present was satisfied of a clear *fluctuating limpid fluid in large quantity* within the malignant production. Dr. Mott, as usual, was slow to express an opinion, and waited for the demonstrations of his unerring scalpel. The story was soon told, and we think to the astonishment of all.

There was first a regularly formed outer tough fibro-membranous covering of considerable thickness: next came another stratum *an inch thick*, of hard semi-transparent, homogeneous gelatino-albuminous tissue, (similar to what is sometimes seen in the hypertrophy of the bronchial glands at the bifurcation of the trachea,) and finally, within, and close and next to this last, and forming the central nucleus of the tumor, and about three inches in diameter, a red, semi-transparent globose mass of softest friable coagula apparently, and no doubt in fact the residuum of an ancient hematocele,—but *no water* any where between these strata or none to speak of, sufficient to convey the slightest degree of hydropical fluctuation properly so called. It was the *coagula*, or as I conceive the debris of coagulated fibrinous blood that imparted the deceptive sensation of fluctuation, and which fluctuation was in truth, as far as my own examinations went, precisely of the *tremulous* or oscillatory character already mentioned.

It was our intention, but for the size of this volume to have inserted under the article of *laryngo-thyroidal bronchotomy*, a highly important case, in which a large shawl or hair-pin near two and a half inches long, and with a head the third of an inch in diameter, and lying with its head upwards, and playing up and down in the larynx, was successfully extracted by Dr. Mott, from a child aged about three years, the daughter of Lieut. Governor H——, of Connecticut. We have however, in a note (p. 656, 657, vol. I.) alluded to the important and neglected practical point to be attended to in such operations, especially in children, viz. the danger of cutting carelessly down into the air passage through the engorged tissues, and the necessity of guarding with the utmost precaution against the slightest admission of blood into the respiratory tube.

We could also have expatiated upon the recent, still more remarkable operation, in which a gold piece of coin, viz., a *half sovereign*, was by an ingenious contrivance of Sir Benj. Brodie in inverting the body, successfully removed from the larynx of a son of Mr. Brunel the celebrated English engineer, after all hope of recovery almost had been extinguished. This case however, has been so frequently detailed in the principal publications both in Europe and America, that the mere allusion to it at present may suffice, until the opportunity shall present of another edition of this work. We will now, until such event may arise, bring this work to a final close, with the single expression, that my respected associate and myself, can both conscientiously declare, that without fear or favor, we have endeavored, to the utmost of our ability, to fulfil in a proper manner all that we promised, and to present to the profession, to the practitioner as well as to the student, a complete and systematized elementary treatise on Operative Surgery, embodying all its most valuable history and processes down to the present moment, in such purity of diction, and upon principles so orthodox, that it might be deemed worthy for a long time to come, to occupy a permanent rank in the hands of every person devoted to this now-absorbing and most clearly-defined department of the healing art.

P. S. T.

NEW YORK, February 2d, 1847.

## THIRD VOLUME.

|                                                                                                                             | Page | Page                                                                                                                                          |

NEW ELEMENTS  
OF  
OPERATIVE SURGERY.

SECTION TWELFTH.

TUMORS.

---

CHAPTER III.

LYMPHATIC TUMORS.

I MEAN here by lymphatic tumors, the tumors which are formed by degenerate lymphatic glands, (ganglions.) It is a class of tumors of which, up to the present, scarcely anything has been said in works upon operative surgery. Generally the treatment of them has been confined to topical applications and general remedies, (médications;) but I have long since satisfied myself that surgical processes are frequently their best, and sometimes, in fact, their only remedy. This is also, I believe, the opinion of M. Warren (*on Tumors*, etc., p. 162.) Those tumors which are sometimes the result of a simple hypertrophy of the natural elements of the organ, at other times formed by the establishment of a variable number of clots (grumeaux) of concrete pus, or of tuberculous matter, or of cysts or purulent abscesses (foyers) which are disseminated as it were in the parenchyma of the hypertrophied ganglionic tissue, represent masses which are very tardy in contracting adhesions to the organic layers which surround them. When they have once acquired a certain degree of hardness, and have continued beyond six months or for a year, it is rare that they disappear by resolution, (i. e. resolvents.) They then rest on the tissue like so many foreign bodies, whose internal morbid action, (travail central,) usually very slow, approaches by degrees the neighboring ganglions, (i. e. lymphatic glands or ganglions,) produces an indefinite enlargement, or a fungous degeneration, or suppuration, or ulceration of the primitive masses. We may conceive, then, the advantage which would result to patients if it were possible to destroy such tumors surgically. We have in practice three modes which we may resort to in such cases with some chances of success: These are *crushing*, *setons* and *extirpation*.

## ARTICLE I.—CRUSHING.

The crushing of engorged lymphatic ganglions, which was proposed and put into practice in a certain number of cases by M. Malgaigne, is not so irrational as might at first view be supposed. The tumor broken up (*broyée*), comminuted (*morcelée*), and reduced into a pulp (*bouillie*) underneath the integuments which remain intact, is then placed in conditions similar to those of a tumor formed by clots of effused blood. Permanent compression succeeding to crushing, properly so called, sometimes induces the matters thus broken up to be absorbed, and then resolution is thereby evidently rendered more easy; only that it is unfortunate that the inflammation from being chronic, often passes in this manner into an acute state, and to such degree as to sometimes transform the lymphatic tumor into a true abscess, the healing (*mondification*) of which is then always tedious and difficult. There are also a great number of cases in which the crushing cannot be performed but with great difficulty. It cannot in fact, be undertaken but for tumors which are absolutely external, and for those which rest on some solid point of support.

M. Malgaigne, who has employed crushing only for ganglions of the groin, used for this purpose the thumb or thumbs applied with force and directly from before backwards on each tumor. In proceeding in this manner there is sometimes need of a great degree of force, and most of the tumors cannot be broken up by this mode. There might also, perhaps, be danger in this region of doing some mischief to the femoral artery. In that region, as well as in the axilla, and under the jaw, and in the neck, I have found it answer better, when the condition of the parts allow of it, to seize the tumor between the fingers or between two smooth pieces of pliant wood, and thus to compress it with a sufficient degree of force upon the sides, and successively upon all the points of its circumference. Many lymphatic ganglions, treated by this process, have, as it has appeared to me, restored themselves afterwards with a promptitude which the long duration of the disease had scarcely permitted me to hope for. But I hasten to declare that crushing nevertheless, is a method which is exceedingly uncertain, and one that cannot be attempted but in a very small number of cases.

## ARTICLE II.—SETONS.

M. Levanier, a surgeon of Toulon, asserts that he has succeeded in effecting the rapid dispersion of inguinal tumors of very long standing, by traversing them with small setons. These consist of simple threads, which are passed by means of a needle through the entire thickness of the ganglion, in which they are left to remain for four, five or six days, and then withdrawn to be replaced by new ones in different directions. One, two, or a greater number of threads are introduced in this manner at the same operation or after an interval of some days, in the same way nearly as I have said in speaking of erectile tumors. The suppuration which is established in the track of each of these threads soon reduces the engorgement of the ganglionic tissue,

and the molecular or interstitial absorption of the tumor afterwards continues to go on without interruption to the termination of the cure.

Without conceding as much confidence to this method as M. Levanier, which moreover I have as yet employed but on two occasions, I nevertheless believe it worthy to be made trial of, especially for ganglions that are of little volume, situated in regions where extirpation would be dangerous, and existing in patients who prefer submitting to all the uncertainties of doubtful processes, rather than recur to the resources of a cutting instrument.

### ARTICLE III.—EXTIRPATION.

Up to the present time, lymphatic ganglions have not been subjected to extirpation but by a very small number of surgeons. The reason of this peculiarity is owing to two circumstances: 1, lymphatic ganglions scarcely ever become engorged or degenerate except from the influence of remote causes; so that there are almost always a certain number of them diseased at the same time, and that it is rarely possible to remove them all; 2, considered as the result of the disease denominated scrofulous, they have been deemed to form only a symptom, or indication (*ombre*) of a general affection, so that their removal would remedy nothing, or the least important element only of the malady. In this matter we must understand ourselves correctly. If the lymphatic tumors are in reality imputable to a general constitutional affection, their extirpation should not be attempted. It is the cause which we must first attack and not this feeble symptom. Nor should we moreover extirpate them, when, notwithstanding they have been produced by an external cause, they are numerous and diffused, [*disséminées*—i. e. existing in various regions. T.] But if there be one only, or if notwithstanding their number, they are well isolated and easy of dissection, we are not to hesitate. If there is reason to suppose that the constitution is good, and that the interior of the splanchnic cavities is not compromised, their removal offers incontestable advantages. Different also from cancerous tumors, degenerate lymphatic tumors possess also this remarkable feature, that the extirpation of those that are most diseased or most voluminous, rather favors than prevents the diminution (*dégorgement*), resolution or dispersion of the others. Thus have I frequently confined myself to the extirpation of a single one, or of a certain number of these tumors, though I knew perfectly well beforehand that I should be obliged to leave many others. Having thus extirpated those which were ulcerated, or very salient externally, or those which occasioned most inconvenience and deformity, I have frequently noticed that the others continued in the same condition they were before, or that they afterwards imperceptibly disappeared. Moreover, those that have advanced farthest being destroyed, nothing prevents our healing the others by the same topical applications, and of submitting the patient to the different courses of general treatment which are deemed to possess the greatest efficacy. When we reflect upon the manner in which these tumors terminate by suppuration, and upon the character of the ulcers, burrowings (*décollements*) and cicatrices which they establish in the skin, even when they get well without an operation, we may well be permitted to consider the

advantages which their extirpation might procure. The extirpation having been once decided upon, there is no serious preparation required for the patient: if the skin is not changed and the tumor be not of a large size, we may confine ourselves to a simple incision of the integuments. In the contrary case, we comprise the degenerated tissues in an elliptical incision more or less elongated, as in the extirpation of any other kind of tumors. In the place of the T or crucial incision which are generally preferred when the tumor is of a large size, I am in the habit of substituting the semilunar incision, so as to construct a flap which is reversed from the free border to the base, and which allows of every possible facility for the rest of the operation. The incision of the integuments having been effected, the surgeon proceeds to the dissection of the tumor. In the event of this being occupied by cysts or purulent or tuberculous layers, we should be cautious not to excise their tissue. In whatever way we proceed, it is better to hook fast of the tumor with a simple or double erigne, which should be then immediately consigned to the care of an assistant. Then holding the parts asunder by means of the fingers or forceps, the surgeon divides and detaches them with caution by means of a straight bistoury. As these tissues are only superposed upon (*appliqués*) or cling loosely around [*collés*—means here to invest, or to be loosely attached to, T.] the ganglion, it is generally easy to isolate them from it. Also the enucleation [of the tumor] by means of the finger or the handle of the scalpel ought in these cases to be substituted for the cutting instrument, whenever we perceive that there would be any actual danger of wounding the large sized vessels or nerves. On the other hand, masses to be extirpated that have no character of malignity, do not exact that we should extirpate the last portions of them with the same care that we do in cases of cancerous tumors. So that in all cases during the course of the dissection, the bistoury ought to be directed upon the exact limits or circumference of the tumor rather than in an opposite direction. We may for the same reason make use of the fingers for the purpose of detaching or even tearing out the remaining roots of the diseased ganglion, when it is deeply situated, or is found to be implicated with organs which it would be dangerous to approach with the bistoury. In delicate regions, and where the lymphatic tumors are composed of many lobes united by simple pedicles, there is no impropriety in detaching that which presents itself the first, in order afterwards to seize successively upon the others. We thus cause less destruction of parts, and more easily preserve the other tissues. Of all other tumors moreover, the lymphatic or ganglionic are those which the most frequently require a ligature to be applied to their root when we undertake their extirpation. In fact, if, after having isolated their cutaneous surface or circumference, we should have any apprehension in separating the root, that we might open into large veins or arteries which it might afterwards be difficult to reach or tie, we strangulate these tumors as deep as possible by means of a ligature composed of two to five braids of thread, so as to interrupt their entire circulation in such manner as to cause their separation, or to enable us to excise them as we have said under the chapters on *Cutaneous and Erectile Tumors*.

*Dressing.*—After the extirpation of lymphatic ganglions, the *hemostatic* means and the *dressing* of the wound exact the same precautions as after all capital operations. I ought to remark however, that except in a small number of cases, immediate union does not here succeed, and that in attempting it there are more inconveniences than advantages. The wound being almost inevitably anfractuons and constituted of irregular cavities, necessarily presents walls which it is next to impossible to bring into exact coaptation. Their tegumentary borders are closed and agglutinated with facility; but collections of blood, lymph or pus, which are soon established underneath, sooner or later compel us to re-open them, and favor the development of purulent centres, and phlegmonous erysipelas, a hundred times more formidable than a wound which has been left to discharge by second intention. Unless, therefore, the ganglion removed should be smooth (unique) and the wound exhibit great regularity, I would not advise in these cases to attempt union by the first intention. I have now (1838) performed extirpation of lymphatic tumors on near a hundred persons, and none of those who have been dressed in the manner I am about to describe, have experienced serious accidents; whilst I have almost always found phlegmasias and suppurations supervene in those in whom I have attempted the cure by immediate union. I first introduce small balls of fine lint into the bottom of all the cavities, and fill up in this manner the entire wound, which I cover over with perforated linen, then with plumasseaux, compresses and a containing bandage. When the blood flows in abundance, without there being any large arteries to tie, I pile up these balls in such manner that they may exercise a sort of compression under the bandage. I use but a small number of them on the contrary, and such as are of the most pliant kind, when there is nothing to fear in regard to hemorrhage. In proceeding in this manner the dressing is prompt and easy, and the results simple. At the end of two or three days we may, without inconvenience, remove the whole dressing down to the perforated linen. A day or two more gives time for the exudation from the wound to saturate the balls which fill it, and to allow of our removing them without any effort and without occasioning any serious pain. Each day we deposit in the wound a less quantity of these balls, and nothing is so rapid as cicatrization in these cases, so much so in fact that most of the patients are cured in the space of from fifteen days to a month. It is besides remarkable that out of near 100 patients operated upon by me for these kinds of tumors, there are up to the present time, but three who have died. I am so much the more surprised at this, because in a great number of them, the operation was long, laborious, painful and really serious. Though in some of these patients there still remained other degenerate lymphatic ganglions, though in two or three of them these new tumors continued afterwards to undergo a great enlargement, it is certain that in the great majority of cases, the cure was prompt and radical, and that the ganglions that were left have, in the greatest number of instances, ultimately retrograded, by gradually re-assuming their natural condition. Up to the present time I have performed extirpation of lymphatic tumors only in the inguinal, humeral, axillary, supra-clavicular, sub-maxillary, parotid and sterno-mastoid regions.

### § I.—*Ganglions of the Groin.*

Lymphatic tumors of the inguinal region present three modifications, which it is important should not be confounded: those which are connected with a venereal affection; those which depend upon some disease of the foot or leg; and those which belong to the class of cancers. In those cases where their origin depends upon a syphilitic infection, we must never, however ancient they may be, attempt their extirpation before having submitted the patient to the specific treatment of venereal disease. If the alteration of the lower limb which has been the cause still exists, it is also prudent when practicable, to effect the removal of this before every thing else. But if, when these precautions have been attended to, or are not practicable, the tumor is hard, of a certain volume, and has existed more than six months, after having been unavailingly attacked by topical applications and the suitable general remedies, then is the operation indicated, and it becomes proper to perform it. We should not nevertheless under these circumstances, undertake it in cases of cancerous affection, or where the chain (chapelet) of lymphatic ganglions which is prolonged into the iliac fossa was at the same time implicated in the least degree of engorgement. In cases of hypertrophy, however, or of simple degeneration whether fungous or tuberculous, a slight degree of engorgement of the supra-inguinal ganglion would not be a formal counter-indication; as the removal of the principal tumor would have the effect in many cases to cause it to disappear. The extirpation of lymphatic tumors in the groin is one of the delicate operations of surgery. The proximity of the crural artery and vein, and their branches, and of the internal saphena vein, and the femoral nerve, will always render it difficult and formidable. The dangers it involves are nevertheless not the same in all cases. So long as it is a question only of sub-cutaneous ganglions, it is in fact possible, with a little address and anatomical knowledge to accomplish it without danger; but if the deep-seated ganglions formed the tumor, it would become necessary to renounce it, or to decide upon tying the vessels on the side of the iliac fossa, for chance alone would enable us to avoid them during the operation. When we operate for the extirpation of the lymphatic glands enveloped in the sub-cutaneous fascia, we may also find ourselves placed in two different positions. Sometimes in fact, it is the sub-inguinal ganglions that are to be extirpated, while in other patients it is the glands in the inguinal groove itself.

A. *Sub-Inguinal Tumors.*—Here the tumors have no relation with the crural vessels properly so called; they are separated from them not only by the fascia lata, but moreover by the internal border of the sartorius muscle. It is upon the line of the saphena vein that they are situated, and not in the direction of the crural artery, unless however, they should be prolonged as far as to the external orifice of the crural canal above. The patient being placed upon his back, should have the limb reversed upon its outer side and moderately flexed. An assistant fixes it in this position, while another looks to and prevents the movements of the pelvis. The surgeon placed on the outside and provided with an ordinary bistoury, divides the integuments from above downwards for the right thigh, and from below upwards for the left thigh,

as has been said above. We might in like manner place ourselves always on the right, in order that the incision might always be made from above downwards, or on the left side if we preferred performing it from below upwards for both sides. We may go with the first cut and without fear down to the sub-cutaneous layer. After having isolated each side of the wound from the corresponding parts of the tumor, we raise up the latter and give the erigne to an assistant, who should carefully follow all the movements of the operator. After having dissected it upon its sides to nearly as far as its root, the surgeon detaches it by small cuts from below upwards, and in such manner as not to wound the internal saphena vein. If, however, the situation of the tumor, or any particular circumstances should have led to the wounding of this vein, it would suffice to compress it below, and afterwards to manipulate the instrument with extensive strokes, in order to terminate the operation rapidly. Nevertheless the surgeon ought to be then aware that in this region the upper end of the veins sometimes gives rise to a pulsating (saccadée) hemorrhage, sufficiently obstinate to oblige him on his part to compress the artery, or even to apply the ligature to it. However, it rarely happens but in approaching their upper extremity, that it becomes advisable to adopt serious precautions in relation to the arterial vessels. Upon the supposition that we should have occasion here for the semilunar flap of which I have spoken, it would be better to turn its free border inwards than to the outside; in the same manner that we should divide the inner rather than the outer lip of the simple incision, if we preferred using the T incision. As to the dissection of the ganglions themselves, prudence requires that we should perform it on the inner side first, then on the outer side, then from below upwards, and to terminate at the inguinal extremity. In this manner nothing would then prevent us, should they appear to be prolonged by means of a pedicle into the crural canal and to the side of the vessels, from strangulating their root before completing their excision. If immediate union can be attempted after extirpation of lymphatic tumors, it is assuredly in the region under consideration. We should have recourse to it if the wound is regular, if the cutting instrument has sufficed for the division of all the tissues, and if after the ligatures are applied, the sanguineous exudation has a tendency to cease of itself. For this purpose the limb is straightened, after which, by means of a sufficient number of strips of adhesive plaster, we approximate and keep in contact the two lips of the wound. A perforated linen, a large gâteau of lint, and some turns of the roller bandage with a spica to the groin, complete the dressing. In the contrary case, the solution of continuity is filled with small balls of lint before applying the other portions of the dressing of which I have just spoken. In either case, we afterwards place the ham and the leg upon a pillow in a moderate state of flexion.

**B. Inguinal Tumors.**—In the fold of the groin, lymphatic tumors are situated sometimes on the inner and sometimes on the outer side, or on the side towards the pubis or that of the spine of the ilium, and sometimes even on a line with the femoral artery. This difference of situation as may be imagined, renders their removal either very simple or exceedingly difficult: In a man in whom ten months before I had

extirpated a cerebroid cancer from the scrotum, I was obliged to remove a tumor of the same nature which had developed itself in a lymphatic ganglion external to the symphysis pubis, and which, having acquired the volume of the first, had extended outwardly as far as upon a line with the femoral vein. In another case I saw a purely lymphatic tumor which occupied the entire space comprised between the antero-superior spinous process of the ilium and the track of the vessels. A woman upon whom I operated in 1836 at the hospital of La Charité, had in the fold of the groin a lymphatic fungus of the size of an egg and which had been ulcerated for more than a year and was situated in the front part of the crural canal itself. Such facts are not rare, and it would be easy for me to show numerous examples of them. To perform the operation the patient should be placed and held as in the preceding case. Nor can any precise rule be given here for the direction of the incision of the integuments. If the straight incision would answer, it should be made in the direction of the fold of the groin or of the long diameter of the tumor. If the curved incision should be preferred, or become necessary to be employed, the free border of the flap must be made upon the outside and below, in which direction also the outer lip of the first incision should be divided, provided the T incision should be thought most advisable. Internal tumors should be dissected in the manner of sub-inguinal tumors, first upon the inner side, then outwardly, and finally from below upwards. The external ganglions should be dissected by a rule directly the reverse, and this in order to reserve for the last thing the most delicate stage of the operation, to wit, the isolation of the tumor at the most proximate point to the vessels. By means of these precautions we may proceed without any very great degree of danger as high up as to Poupart's ligament, or on a line with the apex of the fossa iliaca. When the diseased ganglion occupies the middle of the groin, we isolate it successively upon its two sides up and down, in order not to lay bare the pedicle until the last thing. So long as the surgeon, in order to effect this, is not obliged to divide the aponeurosis, there is nothing to fear, and should the tumor not be prolonged into the iliac canal, he may cut off its root without a previous ligature. But should he at all apprehend the extension of the pedicle of the tumor to the neighborhood of the trunk of the saphena, he will, after having reduced it to a small volume, surround it with a ligature and strangulate it with force before excising the ganglionic mass on the outer side. In the case of the woman I have just mentioned, I was obliged to lay bare the saphena vein as far as its entrance into the crural vein; but by dissecting the tumor horizontally I was enabled to isolate it without any ligature, though the artery was afterwards noticed upon the inner side of the bottom of the wound. I would not hesitate, therefore, to attack lymphatic tumors in this manner, even in the iliac fossa, should they be prolonged to that part, provided they were situated externally to the vascular trunks. Even if it were necessary I would divide the ligament of Fallopius, in order that we might by means of the finger, tear out these tumors or enucleate them in such manner as not to run any risk of wounding the principal arterial branches. But as I have already said, I would no longer hazard such an attempt if the tumors were cancerous, or the vessels surrounded as it were by the

tumors, and that there was ground for believing that there existed degenerate ganglions in the neighborhood of the lumbar region. The dressing in the groin presents some difficulties in addition to those of the preceding case. The application of adhesive straps in this place offers but a feeble resource. The tissues of this region are less homogeneous, and the disposition of the skin there is very illy calculated for primitive agglutination. Nevertheless, if the wound is uniform and in the direction of the inguinal groove, a slight flexion of the thigh may be found sufficient to maintain the two lips of the wound in coaptation. With this exception the dressing flatwise, by means of small balls of lint, the perforated linen, the gateau of lint and the spica, appears to me to be decidedly preferable.

[Having purposely devoted a great deal of personal investigation and practice while at the Seaman's Retreat Hospital, to dressing the ugliest kind of shelving, jagged and leaden-edged, deep, sinuous, and irregular wounds left in the hollow of the groin in syphilitic cases, by burrowing abscesses and discharges succeeding to buboes and mercurial drugging, and where the wound penetrated sometimes to the depth of an inch and a half or more, and as high up as the crural arch and inguinal canal; I can testify to the pre-eminent advantages of *tight, forcible strapping* by multiplied and very long strips of adhesive plasters, decussating each other on the abdomen and down and across the thigh in every direction, so as to form a firm *stellated* support, or covering, requiring only a slight inward flexion of the thigh and persevering use of this mode to hasten granulation from the bottom, and a perfect coaptation of the edges with great rapidity and without the necessity of any auxiliary means but stimulating injections every few days this dressing is renewed. If they succeed thus with the general constitutional treatment in such desperate chronic anfractuous and *cavernous* wounds, surely they should never be neglected in the fresh wound left by extirpating lymphatic glands. T.]

## § II.—*Lymphatic Tumors of the Arm.*

Although lymphatic tumors may become developed upon the track of the cephalic vein and in the deltoid region, it is nevertheless almost exclusively upon the inner side of the arm that these tumors have been noticed. Here they may be found at all the different points of the track of the artery. Nevertheless it is at an inch or two above the inner condyle that they are most frequently met with. To extirpate them in this region the arm must be held off from the trunk, and the fore-arm extended in supination. A longitudinal incision ordinarily suffices. Commenced above and terminated below the tumor, it almost always allows of our arriving immediately upon the pedicle of the latter. It is moreover important during the dissection, that the lymphatic mass should be properly drawn out from between the lips of the wound by an assistant provided with an erigne, while another assistant should always stand ready to compress the brachial artery in the direction of the axilla. The tumor having been detached from the biceps in front and the triceps behind, may afterwards be isolated upon its deep-seated face without any very great difficulty, and without the danger of wounding any-

thing, if the surgeon is careful to carry the point of his bistoury parallel with the plane of the interior surface of the arm, and to graze with accuracy the ganglionic tissue. The ulnar nerve, the median nerve, and the brachial artery, which it quite frequently touches, would nevertheless oblige him to strangulate the pedicle of the tumor with a strong ligature, should it send off any prolongations between them, or should it appear too difficult or dangerous to complete its enucleation either with the fingers or the handle of the scalpel. Here also union of the wound by first intention, offers some prospect of success. Circular strips of adhesive plaster and a graduated compress on each side, the perforated linen, gateau of lint, square compress, and roller bandage, will always offer a facility for this, unless there should be particular difficulties in the way; we should therefore have recourse to it in the greater number of cases. If however, the slightest accident should supervene, or the least difficulty interfere, we should recur immediately to the small balls of lint and the simple dressing. The limb is then placed in semi-flexion and upon a cushion or pillow, until the stage of the primitive accidents has passed by.

### § III.—*Lymphatic Tumors of the Axilla.*

The hollow of the axilla is a region where the lymphatic ganglions frequently become engorged and degenerate. Diseases of the breast and all those of the thoracic limb, occasion there a sympathetic action (retentissement), which makes the hollow of the axilla the locale (centre of an infinity of tumors of different kinds, but which almost all of them, have the lymphatic ganglions for their seat. If it be true that surgeons rarely decide upon extirpating these kinds of tumors, it is in part owing to their nature, which does not allow of our always considering them as a local and independent disease, and again, because the operation is in itself of a delicate nature, and one which is in reality serious. The axillary vein and the branches which it receives in the first place expose us to a sufficiently abundant hemorrhage when we happen to wound them, and afterwards there is danger of that introduction of air which appears so frightful and so difficult to prevent in certain regions, (see Vol. I.) The artery of the same name which it may be impossible to avoid, and the nerves of the brachial plexus also constitute so many circumstances to arrest the hand of the operator. In adding to these that the manipulations of the bistoury are also necessarily restricted by the arrangement and relations of the pectoral muscles in front, those of the shoulder behind and on the outside, and of the chest on the inner side, we have a sufficient explanation of the reserve exhibited by surgeons in this matter. Having, however, frequently encountered lymphatic tumors of the axilla which nothing could disperse, and which were gradually conducting the patients to the tomb, I have thought nevertheless that I could surmount those objections, and now extirpate tumors of the axilla, after the same indications as those for the inguinal region; it is in fact an operation which, since the year 1837, I have performed a great number of times, and under circumstances greatly diversified. From whence I have acquired the conviction that this operation, as I am about to show, is in fact much more frightful [effrayante, i. e., in ap-

pearance, T.] than in reality dangerous. Many of the patients upon whom I have performed it, had tumors of an enormous volume, which raised up the pectoralis major, surrounded the brachial plexus and vessels, or were prolonged at their upper part as high up as the supra-clavicular depression. Out of an aggregate of about 25 examples which I could enumerate at the present time, there have been only two cases of deaths; one of which was a young woman upon whom I operated in 1828 at the clinique of M. Bougon. The tumor, which was of the size of the head of an adult, completely filled the hollow of the axilla, ascended as high up as above the clavicle, and required an extremely extensive dissection. The patient, after having exhibited some encouraging indications of a cure, was seized with a pleuritic effusion and died at the end of three weeks. The second patient was a woman nearly sixty years of age. All the ganglions of the axilla had to be torn out, one after the other; an enormous cavity was the result, which, however, was in great part filled up when a diffused (ambulant) erysipelas supervened and carried the patient off. A third patient who had undergone a similar dissection, died at the expiration of two months, in consequence of accidents disconnected with the operation. All the others operated upon recovered, the most of them very rapidly, that is to say, within the space of fifteen days to a month or six weeks. An inconvenience which retards the cure in this operation, where we are obliged to liberate the part from its ganglions, is the interruption to the circulation of the lymph, and a tendency to engorgements and infiltration of the hand and fore-arm. There may also result from it so great a contraction of the hollow of the axilla, that the movements of the shoulder and the separation of the arm, especially from the trunk, may be greatly obstructed. The manner of performing the operation, though varying according to the size and precise situation of the tumor, is, however, reduced to two processes: one which consists in penetrating into the hollow of the axilla without dividing the muscles; the other in dividing at first through the lower border of the pectoralis major muscle, or even the whole thickness of the two pectoral muscles as high up as to the neighborhood of the clavicle.

A. *By the hollow of the axilla.*—It rarely happens that the incision at the hollow of the axilla does not answer for the operation in question; the preferable position of the patient being upon a bed, rather than seated on a chair. One assistant is to draw the arm towards him, while another stands ready to compress the subclavian artery upon the first rib. The surgeon, provided with a straight bistoury, makes his first incision which comprises the entire length of the great diameter of the hollow of the axilla, and extends from the upper part of the arm to below the tumor or even to the side of the chest. Upon the supposition that this first incision will alone answer for the whole dissection, it is better to place it rather behind than too near the anterior border of the axilla; in the contrary case, should it become advisable to divide its posterior border, it is more proper to place it altogether in front. Having thus divided the integuments, sub-cutaneous fascia and aponeurosis, we introduce a finger into the wound to serve as a guide for the simple or double erigne, which is immediately to hook up the mass to be removed. The surgeon then dissects the

tumor in front, and behind, and on the inner side, and finally from below upwards, in proportion as the assistant draws upon it in the direction required. Having arrived into the hollow of the axilla itself and upon the side of the arm, I have often succeeded in detaching it completely by means of short strokes with the bistoury, while the forefinger of the left hand directed backwards and deep, by raising up the brachial plexus or the vessels, acted as a director. This stage of the operation, which sometimes enables us to dissect the important organs in the hollow of the axilla in the same way as for an anatomical preparation, is too delicate and hazardous to permit me to lay down a general precept. The best mode then is to tear out gently, though with force and by means of the finger, all the lobules of the tumor which appear to be interspersed among the vessels or nerves, or which are prolonged to too great an extent in the direction of the clavicle and the regions of the neck. Should the engorgement of the ganglions be prolonged only by a pedicle above and to the outside, it would be still more easy to surround it with a triple thread and to strangulate it forcibly, in order to excise the whole gland immediately below it. By means of these precautions we remove with promptitude and facility, tumors which do not exceed the size of an egg. We also extirpate without danger or any very great difficulty, those which are too much enlarged and which present themselves under the aspect of bunches of grapes when occupying principally the thoracic wall of the axilla. There are no real difficulties or dangers therefore but for those tumors which rest against the root of the arm or articulation of the shoulder, and for those which are prolonged to above the clavicle. Ordinarily during the entire operation there are but a small number of arteries opened. These are the branches of the external mammary artery, those of the anterior (anterieurs) thoracic arteries, of the common scapular artery, and rarely the internal circumflex artery. We might apply the ligature to them in proportion as they are divided, but there is but little inconvenience in causing them to be covered temporarily by the extremity of a finger, and in waiting until the end of the operation before tying or twisting them. I have no need of remarking that if unfortunately the axillary artery should have been wounded, as in the case mentioned by M. Wolf, (*Graefe und Walther Journal*, t. VII., p. 261.) it would also become necessary to apply the ligature instantly. The hemorrhage at this time, which is most troublesome, is almost always furnished by the veins; so much the more so because in the axilla as in the groin, the venous reflux which might under these circumstances extend back even to the heart, is not yet entirely annihilated. This kind of hemorrhage moreover which we first arrest with the finger, afterwards readily yields to tamponing and compression. The proof of this I have from having seen the axillary vein itself opened in an operation of this kind. I lay it down as a principle not to attempt immediate reunion in these cases. For they are of those in which the extirpation of the lymphatic tumors leaves a cavity too anfractuous and a wound too irregular to make it possible to hope for primitive agglutination. I place therefore small balls of soft lint upon all the points of the traumatic cavity, until it is well filled with them and that they produce a certain degree of compression, should it seem requi-

site to adopt any precautions against the flow of blood. A perforated linen, a gateau of lint, and one of the ordinary bandages for the axilla, serve to complete and to sustain the dressing.

B. *In front of the axilla.*—If owing to its absolute volume or primitive situation it should become impossible to enucleate the tumor by the hollow of the axilla; if, as I have seen it in attendance with MM. A. Bérard and J. Cloquet, in a young subject aged ten years, the tumor should appear to be situated between the two pectoral muscles, or seem agglutinated as it were upon their posterior surface, it would be better to divide the anterior wall of the axillary region than to operate in the manner I have just described. In a young girl whom I have spoken of farther back, and whom I operated upon in 1828, it became necessary to divide the tissues obliquely from above downwards and from before backwards, from the inner third of the clavicle to the lower border of the latissimus dorsi muscle. Another incision parallel to the posterior border of the axilla thus circumscribed four flaps, two smaller which I reversed downwards and backwards, and two very large which I dissected, reversing one of them upon the side of the sternum, and the other upon the shoulder. These two last, comprising the entire thickness of the pectoral muscles, enabled me to detach little by little from the front part and side of the chest, the totality of the tumor, which it afterwards became necessary to isolate behind from the sub-scapularis muscle, from the border of the clavicle above and in front, and from the whole brachial plexus on the outside, and finally to extirpate it from the supra-clavicular depression, where one of its roots of a sufficiently large size had been prolonged. We might here easily avoid the necessity of posterior flaps by substituting the T for the crucial incision. The horizontal branch of the T being placed behind and parallel to the posterior border of the axilla, would put it in our power to fall upon it with an incision which would be vertical or more or less oblique, and which should set out from the front part of the clavicle. The two large triangular flaps circumscribed in this manner, would give every facility desirable, and would accommodate themselves in a remarkable manner to every possible mode of dressing. If the tumor should be more projecting in front than above, it would be practicable to lay it bare with still greater ease by means of the semilunar flap of which I have so frequently spoken. The free border of the half-moon in this case might be turned downwards towards the axilla, inwards towards the sternum, or outwards towards the arm, according to the form of the tumor or the particular indications. It would be necessary for the same reason to cut it out upon a curve of greater or less depth, and more or less elongated. This flap, being raised up upon its base, would allow as readily as the others of dissecting out the tumor up to its termination, and would be attended with the advantage of reducing the operation in fact to the condition of a simple incision. The section of the fleshy fibres which might here interpose, presents nothing in itself serious. What I have said of the division of the tendons and muscles (see Vol. I.) is sufficient to show that misapprehension had prevailed in this matter. If the operation, therefore, by this division would be made more simple and less dangerous, we ought not to hesitate; we should operate also

in front rather than at the hollow of the axilla. The dressing after extirpation of tumors of the axilla by this process, enables us better than the other to undertake immediate union. Whatever may be the form of the flaps, they should be brought together and approximated in such manner as to leave a void only at the depending point of the axillary cavity. They are to be consequently replaced in such a way as to reconstruct, as completely as possible, the anterior wall of the axilla. But I would recommend to leave a meche or tent, or some rouleaux of lint between the lips of the lower part of the wound, so as to provide at that place for the egress of the discharges. This mode of reunion is effected at the axilla as every where else, by means of simple strips of adhesive plaster, aided by position or the suture. I ought to remark before concluding, that in operating at the hollow of the axilla, should the simple incision not answer, we might equally substitute with advantage for the T or crucial incision, that of the semilunar, taking care in that case to turn its free border backwards and outwards. In whatever way the operation and dressing may have been performed, the arm should be kept immovable and slightly raised up towards the shoulder. After the first dressings, it is important, however little the purulent matters tend to stagnate, to open a passage for them. It is at this period therefore that we must prevent the too rapid union of the lower portion of the wound, separate the arm a little from the trunk, substitute emollient cataplasms for the lint, or even have recourse to emollient and detergent injections into the traumatic cavity. Acting upon these principles I have frequently removed tumors from the hollow of the axilla, which many practitioners had refused to extirpate. (Dufresne, *Journ. Hebd.* 1835, t. IV., p. 276.) The tumor in the form of a bunch of grapes, which almost equalled the size of an adult head, and which M. Goyrand (*Lancette Franc.*, t. II., p. 256) successfully removed under the impression he was operating for a scirrhus, was probably a lymphatic tumor. M. Lallemand (Lafosse, *Clin. de l'hôpital Saint Eloi*, p. 4) who employed the suture to unite the wound, and who also supposed he had extirpated a cancerous tumor, likewise as it appears to me removed only degenerate lymphatic ganglions. Though no one moreover up to the present time had laid down precise rules in respect to the operative manual in the extirpation of tumors of the axilla, it is nevertheless true that some surgeons occasionally had recourse to this operation. We already find even in F. de Hilden the rule to cut down upon them, and to draw them towards us and tie their pedicle deep down, before completely detaching them from the body. It would be abusing the patience of the reader to say now that we should proceed in the same manner for scirrhus, colloid, encephaloid, melanotic, fibrous, fungous, or any other form of tumors other than those that are lymphatic. The only point which it is important not to lose sight of under such circumstances, is this, that we should not undertake the extirpation of *malignant* tumors, if the least particle of them is to escape from the action of the bistoury or the ligature in mass; while tumors purely ganglionic or tuberculous, may be extirpated with considerable chances of success, even though we are forced to abandon some of the engorged ganglions in the axilla or above it.

§ IV.—*Lymphatic Tumors of the Neck.*

There exists in the neck so great a number of lymphatic ganglions, and these ganglions are distributed upon so many different points, that it is scarcely possible to study their extirpation separately in all the situations in which they sometimes give rise to the formation of abnormal tumors. It has happened to me on two or three occasions to extirpate them where they were situated behind the sterno-cleido-mastoid muscle, and seemed to repose upon the outer side of the trapezius. In that position we may lay them bare freely by a simple incision, directed from above downwards or a little obliquely. As in this region there is no important organ to avoid, we may, after the incision of the integuments is made, and the tumor is properly secured with the hook, proceed with free and rapid strokes of the bistoury. From the natural tension of the parts rendering it almost impossible to keep in perfect contact the walls of the cavity which results from this operation, we have the reason why immediate reunion scarcely ever takes place, and that it is more prudent in fact to dress flatwise and with small balls of lint, rather than by the exact approximation of the parts. If, as I have seen in two or three cases, the tumor, which was in all situated behind the sterno-mastoid muscle, should occupy the upper third of the neck or the neighborhood of the occipito-mastoid region, we might proceed otherwise, and treat the division of the integuments as an ordinary simple wound. Between the os hyoides and thyroid cartilage, where lymphatic tumors of the neck are sometimes developed; between the sternum and the thyroid gland, where they have also been met with in some patients, they should be treated as will be mentioned in the article upon operations which are performed upon the neck. But it is necessary to consider the extirpation of lymphatic tumors separately, in the parotid, sub-maxillary, carotid and supra-clavicular regions.

*A. Parotid Tumors.*—Having to treat elsewhere of the removal of the parotid itself, when this gland is degenerated, I could only repeat here the details into which I shall then be obliged to enter,—(see *Extirpation of the Parotid*, infra.) I will say only in anticipation that those tumors formed by the parotid gland of which so much has been said, have all of them, or almost all of them, for their basis or point of departure the lymphatic ganglions properly so called. It is from having frequently ascertained the truth of this position that I take the liberty at the present time to affirm it positively.

*B. Sub-maxillary Tumors.*—The sub-maxillary tumors that are most common, are observed in the mylo-hyoid space; but they are met with also directly under the chin, quite frequently under the angle of the jaw, and sometimes also upon the external face of this bone in front of the masseter muscle. In a young girl aged ten years, who had one of the size of a large nut under the chin, I made an incision, which being carried from the symphysis of the jaw to the level of the os hyoides, while the head of the child was held back by an assistant, enabled me to hook fast, dissect out and completely extirpate the tumor with ease. The wound which was united by first intention by means of a band of adhesive plaster passed under the jaw in the

form of a bridle, was completely closed up in less than fifteen days. In another patient who had one of them on each side the median line, it became necessary to make two such incisions. As these tumors were in part softened and as they left quite an irregular cavity, I deemed it advisable to dress them with small balls of lint and to treat them by secondary reunion; the cure nevertheless was completed at the end of three weeks. The lymphatic tumors which at this part are sometimes sub-cutaneous, at least situated in front of the muscles, are not approached by any large sized artery. The sub-mental is the only one that may be wounded and require a ligature. Nevertheless there sometimes exudes from the wound a sufficiently considerable amount of blood to oblige us to give the preference to tamponing to dressing simply with adhesive plaster. Under the angle of the jaw the ganglions may acquire the size of a nut, egg or fist. Being in that part situated outside of the digastric muscle, and sub-maxillary gland, and in front of the sterno-mastoid muscle, they approach sufficiently near the internal jugular and the carotid arteries to create some little apprehension in those who should desire to attempt their extirpation. Nevertheless I have frequently removed them and always found that the operation was simple and sufficiently easy. For that purpose, the patient being inclined a little towards the sound side, and having the chin slightly raised up, should be kept in this position by assistants, who should at the same time depress his shoulder upon the diseased side. Should the tumor be of medium size, I lay it bare by means of a curved incision, modelled in some measure upon the curvature of the sub-maxillary region. If the lymphatic mass is of a certain volume, I give to this incision a very decided semilunar form, in order to obtain a flap which may be raised upon the side of the jaw from below upwards and from behind forwards. Having then seized the tumor with a hook, which an assistant is charged with making traction upon in the proper direction, I proceed to the dissection. The finger holds apart and stretches the lamellæ in proportion as the instrument divides them, and when we reach near the deep-seated parts, completes the enucleation should there be any organ there which ought not to be exposed to the point of the bistoury. Whether the wound forms a semilunar flap or a simple curved incision, it ought not to be completely closed except in extremely simple cases. In the aggregate we are exposed to fewer inconveniences when we treat it by gentle tamponing, than when we endeavor to unite by first intention. The tumors on the outer side of the jaw however are sufficiently rare. I have removed some which were situated exactly upon the track of the facial artery. There can be no positive rule for the direction of the incisions in such cases, and the great diameter of the tumor must serve as our guide for their location. We must be prepared moreover to wound the external maxillary artery, inasmuch as it is often enveloped as it were by the ganglions which we have to extirpate; but this vessel is not of sufficient importance to create the least uneasiness, and the surgeon has only need of recollecting that it is generally advisable to tie or twist both its lower and upper end, in consequence of the reflux which takes place from the coronary arteries or the angular artery. The wound here being on a fixed plane might be closed by primitive agglutination, if it

were found in other respects under conditions which would authorize our undertaking this kind of union with reasonable chances of success.

C. *Mylo-Hyoid Tumors*.—The triangular space bounded on the inner side by the mylo-hyoid or the hypo-glossus muscle, outwards and upwards by the inner face of the jaw, and outwards and downwards by the supra-hyoid aponeurosis and the platysma myoides muscle, and in which space is situated the sub-maxillary gland, also includes a variable number of lymphatic ganglions, which frequently become diseased, and sometimes enlarge to such extent as to acquire the volume of an egg or greater. These tumors becoming developed in consequence of diseases of the face or anterior region of the cranium, or of the interior of the mouth or of the gums, frequently exist under the character of a local affection in persons, who in other respects, are in the enjoyment of good health, and who have no other kind of lymphatic engorgement. It is in such cases that I have most frequently practised extirpation of the glands of the neck, and where the operation succeeds the best. In addition to the examples which I have elsewhere published, I could at the present time add a great number of others. The tumors of which I speak are globulous, generally ovoid, movable, hard or elastic, and exceedingly prominent below the jaw. In pressing them at the same time through the mouth and at the supra-hyoid region, one would suppose that they were isolated (à nu) under the mucous membrane and under the skin. But this appearance should not deceive us. Lymphatic tumors of the sub-maxillary region, are necessarily sub-aponeurotic, and the surgeon must expect to search deeply for them, if he expects to remove every part that is diseased. As for the rest, provided their surface has not undergone any degeneration, is not ulcerated, nor has contracted any unnatural adhesion with the surrounding tissues, the removal of the larger sized ones is not essentially more difficult or dangerous than that of the smaller.

I. The *operative process*, moreover, is sufficiently simple; and the incision of the integuments may be performed in three ways. 1. An incision parallel to the lower border of the jaw or to the great diameter of the tumor, ordinarily suffices; only that it is advisable to place it sufficiently low down, in order that after the operation it may not be drawn towards the base of the bone. The wound being thus reduced to a simple slit, leaves only a linear cicatrix, which is naturally concealed under the jaw, and is scarcely perceptible.

II. If the straight incision should not give sufficient freedom, as happens when the tumor exceeds in volume a large sized pullet's egg, a vertical incision upon the lower lip of the first wound, would procure a division in T, with two lower flaps, which should be dissected and reversed, one to the front and the other backwards.

III. In this case I would still give the preference to the curved incision and semilunar flap, over the T incision. This flap, raised up from the neighborhood of the os hyoides to the face, would enable us to lay bare the entire cutaneous surface of the tumor, and would afterwards fall by its own weight over the cavity of the wound. In whatever way we proceed, the patient being placed upon the bed and inclined as has been described above, should have the chin raised and

the head thrown backward. The incision of the integuments should be made boldly and as far as to the most projecting point of the tumor. Its anterior angle may be prolonged without apprehension of wounding any important artery. But posteriorly it is not the same; there it may be possible that the facial vein, or even the external maxillary vein has been raised up by the lymphatic tumor and rendered more superficial than usual. Most frequently, however, these vessels are situated rather behind and on the inner side of the posterior extremity of the tumor. It is sufficient to say that in these cases, the dissection of the parts should commence from above, or from below, or at the anterior half of the degenerated ganglions. Being secured and drawn forwards and outwards by means of an erigne; these tumors are afterwards disengaged from the bottom of the mylohyoid fossa by means of the finger or the handle of the scalpel, as much as by the cuts of the bistoury. If the facial artery should, as frequently happens, be wounded, there is no cause to be greatly alarmed. The ligature is to be applied immediately, or what is as well, it is to be temporarily closed by the finger of an assistant. Were we not prepared for this, we might in fact, in a great number of instances, suppose that we had opened it, when it is the secondary branches only which enter into the tumor at the apex of the ganglions, that have been divided. The disease sometimes produces such enlargement in these branches that we not unfrequently find them to have acquired the dimensions of a crow's quill, and throwing out blood with violence at the moment that they are divided by the bistoury. We may while dissecting out these tumors be compelled to penetrate as far posteriorly as the sides of the larynx and in front of the carotid arteries. I have frequently seen pulsating naked before the eyes of the operator, and at the bottom of the cavity previously occupied by the tumor, the lingual artery on the inner side, the internal carotid behind, and the external maxillary without. This cavity which at first has something frightful in appearance and which could easily contain the fist, may be prolonged also as far as the median line in front and the os hyoides below. M. P. Eve (*Southern Medical and Surgical Journal*, January, 1838; and *Gaz. Med.*, 1838, p. 17) penetrated in this manner as far as the outer side of the tonsil to remove a tumor of half a pound in weight, and cured his patient. I assisted M. Vidal in a young man in whom he removed three degenerated ganglions which occupied one entire side of the supra-hyoid region. Unless the tumor be uniform and small in size we must not attempt to close this cavity by first intention. Tamponing and the mode by second intention, offer an infinite deal more of security and without materially retarding the cure. It is to be recollected, only that after the first eight or ten days, that is, when the balls of lint become no longer of any use, the upper lip of the wound, drawn upon as it is by the border of the jaw, has such tendency to be raised up towards the face, as to require some preventions. It is then that a strip of adhesive plaster, placed on the outside of and along the lower border of the jaw, serves to retain it and crowd it downwards and prevent its retroversion (*renversement*). This strip would become still more advisable, if in place of the usual incision, we had employed the semilunar flap to lay bare the tumor.

By this kind of primitive secondary union we are protected from erysipelas and purulent collections, while we produce notwithstanding, in the space of fifteen days to a month, a perfect cure, with a cicatrix nearly linear. This mode of extirpation, for which no person had given the process when I pointed it out in the year 1825, has now been performed a great number of times successfully by M. Bégin at Strasbourg, (*Malle Arch. Méd. de Strasbourg*, 1836,) by M. Sédillot, (*La Presse Méd.*, t. I., p. 139,) and by M. H. Larrey at the Hospital of Val-de-Grâce. For myself, there is not a year, that I have not had recourse to it, on from ten to fifteen patients; and I have not seen up to the present time any operation whose consequences are less serious. Every thing goes to show that in this region, the introduction of air into the veins is not to be apprehended, notwithstanding some facts which have been related in favor of a contrary opinion. Unless therefore there should be some particular complication or counter-indication connected with the general constitution of the patient, the extirpation of lymphatic tumors from the sub-maxillary region, should be recognized in practice as a systematized operation of surgery.

*D. Tumors of the Carotid Region.*—After the mylo-hyoid depression and the carotid region, the sterno-carotid groove is that on which lymphatic tumors are the most frequently met with. The chain of ganglions which occupy this groove, is composed of such numerous glandules (grains) that they are noticed on every part of its length from the supra-sternal fossa to the angle of the jaw. They are distributed, moreover, in such a manner, that some repose directly upon the anterior surface of the vessels, while others lie entirely concealed, either by the internal surface or by the posterior border of the sterno-cleido-mastoid muscle. I have, however, never found them to be absolutely superficial, though I have sometimes met with them all around the carotid artery or jugular vein, while others were at the same time prolonged under the posterior surface of the pharynx or œsophagus. If in this region the tumors are numerous, deep-seated, and but little prominent, or should raise up the sterno-mastoid muscle, in place of projecting towards the side of the neck or larynx, it is better not to meddle with them, or to attack them only with general remedies and local applications. If, on the contrary, they present themselves under the form of one or more movable lumps, (bosselures,) making a projection between the sterno-mastoid muscle and the middle of the neck, and if their totality constitutes a mass, independent of the thyroid body, the carotid artery, or jugular vein, without having any prolongation in the direction of the chest, it is allowable and practicable to undertake their extirpation. Upon the supposition that the tumor situated transversely, and strangulated by the sterno-mastoid muscle should be bilobate, in such manner as to present one of its halves posteriorly, and the other in front, there would still be ground to attempt its removal, should the uniting bridle, in other respects, be so thin as to allow of our avoiding the neighboring vessels and nerves. To perform the operation, the patient is to be placed upon his back, taking care that his head is raised sufficiently high upwards. In this position the sterno-mastoid muscle being stretched and thrown backwards, pushes the tumor forward, and in this manner

renders it more superficial, while at the same time it gives it a greater degree of fixity. The surgeon making his incision from above downwards, divides the integuments to an extent which should exceed the limits of the tumor by nearly an inch. As soon as the front part of the tumor is laid bare, he detaches the lips of the wound upon the outer and then upon the inner side. It is at this moment that he hooks his erigne into it, in order that an assistant may secure it, and hold it aside while the dissection is being proceeded with. This dissection has nothing about it particularly difficult until we arrive near the bottom of the carotid region; but setting out from there, the finger should always precede the point of the bistoury, and no lamella of tissue ought to be cut without having been previously stretched by means of the forefinger. By inclining the extremity of the instrument towards the ganglionic surface, we avoid with certainty all the large vessels which are situated behind. I have, moreover by adopting the mode of enucleation, several times succeeded in detaching some more deeply situated lobules, which were entangled behind the jugular vein, or carotid artery, and sometimes between those two vessels. It is, moreover, a matter of little importance, whether the deep-seated surface of the tumor should be isolated from above downwards, or from below upwards. We must be prepared to find by this operation, as has happened to me in quite a great number of cases, that we have extensively denuded the carotid artery, the internal jugular vein, the pneumo-gastric nerve, and the great sympathetic. It suffices to remark that these organs might be interfered with, and that we must be on our guard against wounding them. [See case in our Vol. II, under the head of the *nerves*, in which the pneumo-gastric imbedded in a tumor recently removed by Dr. McClellan, of Philadelphia, had to be completely divided, which, however, did not interfere with the restoration of the patient. T.] It was in a case of this kind that M. Fouilloy (Ansiaux, *Clin. Chir.*, p. 238, 2d edit.) was compelled to tie the carotid artery. There is every reason to believe also, that the tumor successfully extirpated by M. Voisin, (*Gaz. Med.*, 1835, p. 447,) and which obliged him to dissect upon the carotid, was one of the class of those of which I am speaking. We may conceive also, that an opening into the internal jugular vein, would in this part endanger to a greater degree than in most other regions of the body, the introduction of air into the heart, and the fearful accidents which are the consequence of it. In a young man in whom I had removed one of these tumors on the right side of the larynx, there was heard at the moment of my dividing one of the anterior veins of this region, near the jugular, a hissing and gurgling sound, which at first gave me great uneasiness, the more so from the patient uttering a piercing cry that he was dead! There followed, however, no serious symptom, and the consequences of the operation were exceedingly simple. I have already stated (see Vol. I.) that a woman in whom I had been obliged to penetrate as far as to the posterior surface of the pharynx, was seized to an extreme degree with the symptoms which indicate the entrance of air into the veins, at the moment when I had wounded the upper part of the internal jugular. Without asserting that these facts are very conclusive in respect to the

entrance of air into the venous system, it is proper, nevertheless, that we should not forget them, and that we should reflect upon the circumstances which may produce them, when we have decided upon the extirpation of lymphatic tumors in the carotid region. When some of the lobules of the tumor are situated at, and project towards the posterior border of the sterno-mastoid muscle, it is not uncommon to see them have a tendency to move forwards, and conceal themselves to a certain extent under the muscle, in proportion as we extirpate the anterior lobes. Their removal also, greatly embarrasses the operation, and admits of the question, whether it would not be more advisable to attack them separately, by means of an incision, independent of the first, and before commencing the other part of the operation. Having in one case adopted this plan, I found that the rest of the tumor, thus liberated from all kind of adhesion posteriorly, advanced freely forward, and yielded readily to the tractions that it was afterwards necessary to make upon it. In case of still greater complication, as for example, where besides these two lobes, anterior or posterior, the tumor should be exceedingly thick at its neck, I would not hesitate in order to lay it bare, to divide the sterno-mastoid muscle, and in such manner as to transform the entire wound into a large T incision, whose stem should be placed transversely. Here also, more than in the sub-maxillary region, the dressing by second intention should have the preference over immediate reunion. The lamellar character of the tissues, the natural and unavoidable mobility of many of them, and the great number, or the importance of the vessels which have suffered, do not allow in such cases of our counting upon a free primitive agglutination; and the danger of purulent abscesses in the direction of the chest, either above or below, is too formidable to incur this risk by attempting to shut up the wound by first intention.

E. *Supra-Clavicular Tumors*.—The hollow, or species of cavity which is noticed above the clavicle, also contains lymphatic glands, whose degeneration is not uncommon, and which come under the same considerations of pathology, therapeutics and operative surgery, as the preceding. Nor should I, as they are surrounded with numerous or important vessels and nerves, any more recommend their extirpation to be undertaken unless in a case of necessity; the more so, as it is often difficult to ascertain in the beginning, whether they are continuous or not, by chains of the same nature as far as the axilla, or in the direction of the chest. A young lady who had one of these tumors upon the front, and outside of the scalenus anticus muscle, was desirous of getting rid of it. Before being enabled to complete its removal, the surgeon, a celebrated practitioner at Paris, found that it made a prolongation inwards, and that there was a similar one in front of the carotid vessels. In his attempt to extirpate this last, he opened extensively into the internal jugular vein, near its junction with the subclavian. A copious hemorrhage followed: the operation, nevertheless, was finished, but symptoms of purulent infection, or phlebitis, soon made their appearance, and the unfortunate lady perished on the eighth or ninth day, causing to her afflicted relative who was a physician, and greatly attached to her, the most poignant regrets. I would, therefore, not extirpate lymphatic tumors in the

supra-clavicular region, unless they were perfectly movable, isolated, and without any ramification towards the anterior region of the neck, or towards the axilla or thorax. Another reason which would prevent me from interfering with them except under these circumstances, is this, that if the introduction of air into the veins is really dangerous any where, it ought to be so in the supra-clavicular region more than any where else. Up to the present time, I have performed this operation only upon five patients. In three of them the tumor, which did not exceed in volume a large nut or small egg, was so well isolated and movable that there was no serious difficulty to be surmounted. The two others had each a ganglionic mass, which was prolonged as far as the brachial plexus, and subclavian vessels. This dissection was tedious, but no accident supervened, and the cure was completely established. The patient should have the chin slightly raised up, the head inclined towards the sound side, and turned back, and the shoulder of the diseased side depressed, and also directed backwards. The surgeon placed on the same side, makes an incision parallel to the clavicle if the tumor exceeds the volume of an egg; and in the contrary case, parallel to the axis of the body. In whatever way made, this incision should be of sufficient extent not to embarrass the consecutive steps of the operation. Supposing after the first incision we should be under the necessity of making another, we would then freely divide the upper lip of the wound in the first case, and the outer or posterior lip in the other. Perhaps, also, it would be more advisable, in lieu of these different modifications of the ordinary incision, to substitute a large semilunar flap, taking care to turn its free border outwards and downwards. The integuments being now held aside or turned back, the surgeon seizes the tumor with the erigne, and hands it over to an intelligent assistant, that he may raise up or incline the diseased mass according as it may be required during the remainder of the operation. The dissection is also to be performed after the same rules as in the preceding regions. It is better in commencing, to do this from above, then outwardly, than to begin on its inner border or inferior portion, since the internal jugular or subclavian vein lies on one or the other side of it. Having arrived at its deep-seated surface, we should isolate it after the same rules (*dans le même sens*), and here still more than in any other region, would there be occasion for strangulating its root completely below it, if it should appear to be too hazardous to detach it up to its termination by means of the point of the bistoury, and that the finger would not suffice for enucleating it. This operation, which is ordinarily very painful, in consequence of the numerous branches of the cervical plexus, which are dispersed throughout the whole extent of the supra-clavicular region, compels us also, in most cases, to divide the external jugular vein; but this vessel is of too little importance to make us hesitate about sacrificing it. I would not hesitate, then, to divide it in the beginning, and afterwards to tie its upper end and even its lower, if I thought it could cause the least inconvenience. We should have to respect, also, and to tie them should they be divided, the transverse cervical artery, the supra-scapular, the ascending cervical, and even the inferior thyroid. As to the dressing, I would regard it as exceedingly imprudent to wish to run the

risk of union by the first intention. In whatever way we may proceed, the internal surface of the flaps or lips of the wound cannot be applied with the required accuracy against the bottom of the solution of continuity. Suppuration being thus rendered unavoidable, and having no issue, would expose to the risk of purulent abscesses and diffused inflammations, of which it would be difficult to arrest the progress or avert the danger. The flat dressing by means of pliant balls of lint, perforated linen and plumasseaux, secures us from these apprehensions, and does not perceptibly retard the definitive cicatrization of the wound.

Can it be necessary now to add, that lymphatic tumors may be developed everywhere, where there naturally exist ganglions of the same name, and that everywhere also it would be advisable to attack them by conforming ourselves to the rules established in the preceding paragraphs? Until practice shall have acquired a certain extension on this point, it would be useless, as I consider, after having laid down the general rules, to detain ourselves with the projection (supposition) and description of special processes.

[*Lymphatic Tumors* or Lymphatic Cysts, those in fact called by the French *cold abscesses* (abcès froids), have been treated successfully by Dr. G. Capelletti, of Trieste, (*Giornale per servire, &c.*, January, 1842; *Arch. Gén. de Paris*, 4e ser., t. III., p. 346-347.) by means of injections of nitrate of silver (2 to 3 grammes of the nitrate to 500 grammes of water); injecting through punctures first made in various places by the trochar in order first to evacuate the contents of the tumor. The tumor is to be filled with the injection, and the action of the latter aided by uniform and continued pressure.

One of the most remarkable and mysterious cases of a *general hypertrophied condition of all the lymphatic glands* on the external sub-cutaneous regions of the body in an adult woman from one of the provinces of France, aged 38 and otherwise perfectly healthy, occurred to the excellent author of this work, M. Velpeau, in his own service at the Hospital of *La Charité*, at Paris, during the year 1845. These enlarged glands in the only account of them we have yet met with (*Annales de Thérapeutique*, Paris, April, 1845, in Cormack's *Lon. & Edinb. Month. Journ.*, June, 1845, p. 459.) are, it is stated, found in this woman in masses, as it were, or strung in chaplets varying from the size of an almond to a hen's egg, in every region externally where such glands exist, viz.: in the axilla, groins, neck, elbows, legs and trunk. They roll under the finger, are without pain or change of color on their surface. They appeared almost two years before without any appreciable cause. The woman had previously enjoyed excellent health; she is even now robust and suffers nowhere, except that the tongue is a little white, and the digestive organs are occasionally out of order. She says she has lost flesh, but she is still rather stout; the skin has a slightly yellowish tint, but not approaching to icterus; she has perspired copiously through the night for some time past. No one of her family, so far as she knows, has been affected in a similar way, and none of the inhabitants of the country where she resides have any thing similar. Her place of residence is well aired, and from her occupation she

passed most of her time in the open fields. M. Velpeau retained her in his ward as a subject of study; she was put on the extract of walnuts for nearly two months, but no favorable change occurred; the health of the patient seeming rather to decline. This case seems to call in question the pathological accuracy of the opinion that the enlargement of the sub-cutaneous glands is necessarily connected with a scrofulous temperament, and the evolution of which temperament, so far as these glands are implicated, generally takes place in the early period of childhood. In this woman nothing is found but general hypertrophy of the glands; the serous membranes are in a good state, the osseous system exhibits no alteration, and there are no knotty cords in the course of the lymphatic vessels, as is the case in some kinds of erysipelas. It may be termed a sort of general *ganglionitis*; but it does not follow that it is true scrofula, since there are none of its constitutional symptoms. Nor is there any thing of cancer in this case, though this affection is by some thought to have its origin in chronic lymphitis. T.]

---

## CHAPTER IV.

### NEUROMATIC TUMORS (*Neuromes*).

Pathologists have frequently mentioned small tumors, usually sub-cutaneous, the distinguishing feature of which is that of causing from time to time, and upon the slightest occasion, painful irradiations excessively acute, which yield to no remedy and are a source of torment to the patients. These tumors, which many persons have located in the nerves, with which however they must be disconnected, if Dupuytren and M. Wood (*Trans. Med. Chir.* of Edinburgh, vol. III., p. 317), which M. Jaumes (*Thèse* No. 266, Paris, 1828), ranges among cancers, that Boyer was desirous of considering as scirrhus, which are bodies *sui generis*, according to some others, and upon which MM. Arronshon (*Thèse*, Strasbourg, 1822), Clerambeault (*Obs. de Méd et de Chir.*, 1829), Wood, Descot (*Affections locales des nerfs*, 1825, p. 208 to p. 286), and Alexandre (*De tumor nerv.*, etc., Leyden, 1810), have published interesting observations, are much more common than would be imagined according to classical authors. Not having to decide in this place what may be their real character, I will confine myself to saying that for the most part they have been found on the track or in the substance itself of the nervous cords, and that they have sometimes presented themselves to me with the characters of tuberculous masses, and at others under the aspect of tumors that were truly scirrhus or encephaloid in the crude state; while in other cases it would have been utterly impossible for me to have compared them to any other morbid production or degenerate tissue. It is incorrect to assert with Descot (*Op. cit.*, p. 208,) that their size varies from that of a grain of wheat to that of a bean; for I have met with some whose dimensions exceeded that of the fist, and we shall see farther on that other observers

have met with similar examples. It would be more correct to say that their volume varies from that of a grain of wheat to that of the head of a new-born infant. Descot, in his work (*Ibid.* p. 209,) which was prepared in great part under the dictation of Bécclard, commits another error in saying that these tumors are scarcely ever multiplied. M. Wood, in fact, speaks of a patient who had three of them. Siebold had two of them above the instep, and I counted *nineteen* upon the same patient at the hospital of La Charité, in 1836. In giving to these tumors the name of *ganglions*, under which Hippocrates and Galen appear to have designated them, and in the attempt to distinguish them under the name of *nodatio* from tumors called *nodus*, Jean de Vigo has but attempted a futile division; but at the present time not having it in our power to adopt any name to the exclusion of others, they are still designated under the title of knots (*noeuds*) after Parè; *painful sub-cutaneous tumors* as they are called by the English practitioners especially; or *neuromata* (neuromes), or *chondromata* (chondromes), which is the epithet used by Odier, and which has been generally sanctioned by the French pathologists. The accidents they cause, the excruciating (atroces) pains they excite, and their usual resistance to every kind of remedy, induce most patients affected with these tumors to demand of themselves to be relieved from them by extirpation. It is in fact the only efficacious means that surgery has to oppose to them. No doubt that by attacking them with caustic as Siebold the father did upon Siebold the son (Alexandre, *Op. cit.*, p. 21) we may also sometimes succeed in curing them; but the operation by this mode would be longer, less certain and in reality manifestly more painful. Amputation of the part, which Louis (*Encyclop. Méthod.*, partie Chir. t. II., p. 442), Odier (*Manuel de Méd. Prat.* cité à l'art. *Excision des Nerfs*), and M. Warren (*on Tumors*, etc., p. 62), are still in the practice of, would not be justifiable at the present time, unless by means of its degeneration the tumor had effected a profound alteration in the limb. As to extirpation, it would always be easy and simple, if it were true, as the title of *sub-cutaneous tumors* would seem to indicate, that *neuromas* were always found immediately underneath the skin; but observation has now shown that the deep-seated nerves as well as the superficial, become the seat of these tumors. It follows from this that the removal of neuromas may sometimes become a serious operation. They have moreover been encountered upon almost every region of the body. Franco (*Traité des Hernies*, p. 484.) speaks of a woman who carried one for ten years upon the tibia. Another woman, mentioned by Loyseau (*Obs. de Méd. et de Chir.*, p. 56.) had one upon the inner part of the thigh, and the same practitioner met with one in another woman upon the outer part of the same limb. Whether the small nodule removed by Pouteau (*Œuvres Posth.*, t. I., p. 5.) was or was not a neuroma rather than a simple inodular induration, it was found nevertheless, in front of the malleolus at the place where the saphena is opened in bleeding of the foot. M. A. Petit (*Discours sur la douleur*, p. 15, an VII.) also relates that he had met with them almost exclusively upon the legs, though he had seen one also upon the fore-arm. In the case mentioned by Valsalva, as related by Morgagni, (*De sedibus et*

*causis morb.*, epist. 50,) the tumor was situated upon the malleolus. In the case of Cheselden, (*Anat. of the Human Body*, p. 256, tab. 28, fig 7,) it was seated in the ulnar nerve. Petit (*Mém. de l'Acad. de Chir.*, t. I., p. 90,) mentions another in which it existed upon the arm. In one of the female patients of Camper (*Demonstr. Anat. Path.*, lib. I., cap. 2.) it was upon the outside of the elbow; and in another woman mentioned by the same author, upon the front part of the knee. The patient amputated by M. Warren (*on Tumors*, &c., p. 60) had one upon the tibia below the knee. The tumor spoken of by E. Home, (*Trans. for the Improvement of Med. and Chir. Knowledge*, vol. II., p. 92,) and which was removed by Hunter, was also situated upon the arm: and in the patient of E. Home himself, the tumor had to be seized in the hollow of the axilla. A. Dubois, (Spangenberg, *Archives de Hom.*, t. V., p. 306,) in one case saw the neuroma in the neighborhood of the patella, and on the middle of the arm in another. The tumor dissected by Hasselbach (Alexandre, p. 22) occupied the ulnar nerve, and that of Siebold (*Ibid.* p. 21) the space between the two malleoli. Neumann (see Siebold, t. I., p. 54) encountered one on the lower and middle part of the forearm. One of the patients of Rieche, (Alexandre, *op. cit.*), had the tumor on the inner part of the arm, and the other outside of the condyle of the humerus. M. A. Cooper (*Trans. Med. of Edinburgh*, vol. III., p. 640,) and M. Warren (*on Tumors*, p. 63,) have met with them in the breast or below it. Nicod (Descot, *op. cit.*, p. 244,) mentions to have seen them on the chest, and M. Marjolin (*Ibid.*, p. 245,) on the scrotum. In the patient of Short, (*Obs. de Méd.* t. IV., art. 27,) the tumor was situated upon the thigh; while M. Warren, (*on Tumors*, &c., p. 63,) saw one in a boy of sixteen years, below the great trochanter. With respect to myself, I have met with them on the sole of the foot, on the outer side and inner side of the leg, in front and on the inner and outer side of the thigh, twice even in the depth of this limb, on the right and left side of the thorax in two different women, on the right portion of the epigastrium, near the wrist, and on many points of the fore-arm; in the body of the biceps muscle, on the track of the musculo-cutaneous nerve, and in the depth of the carotid region. What I have observed, and which is in accordance with what is related by authors, proves, in contradiction to what Descot (*op. cit.*, p. 210,) alleges, that these tumors are more frequent in adult or old age, than in children. One of the women whom I had an opportunity of examining was sixty years of age and upwards; another was 40, a third 36, and the youngest 21. The same has been the case with the men, who were 30, 40, and 50 years of age, and even older. If one of the patients of Reiche was only 19, the other was 44; those of Morgagni and Petit were young girls, and the cases of Camper, E. Home, and Louis were clearly women. Nor were those of Dubois and Hasselbach young subjects, while the case of Neumann was 60 years of age. These details prove moreover, that if M. Wood has met with neuroma in women only, this must be ascribed to accident only, since numbers of men have also been affected by it. We must add that cases of neuroma have been noticed also by Bicet, Pearson, Broon, Newbigging, Swan, Hall, Windsor, Laing, Walker, Hey,

Simson, Gooch, Jacopi, Monteggia, Craigie, Mojon, Capel, De Haen, Leduc, J. Bell, W. Blizzard, Marandel, Beauchêne, Richerand, and some others, all of which have been collected by M. Wood in his *Memoir* (pages 324, 326, 329, 330, 334, 345, 350, 353, 354, 390) ; and by Descot in his *Monography* (pages 252, 253, et seq.) As to the efficacy of extirpation in neuromas, it is no longer at the present day allowable to call it in question. The woman operated upon by Franco had been for ten years in a perpetual torment. The tumor, which was of the size of a small nut, had scarcely been removed, when the suffering ceased forever. In the two examples cited by Loyseau, the pain, which became excessive as soon as the patients began to get warm in bed, also disappeared immediately after the operation, which the surgeon believed he could render more effectual by afterwards cauterizing the wound. The same result was obtained by Pouteau, though in the case mentioned by this practitioner, the pains were so excessive as to occasion convulsions in the left side. One of the most curious facts of this kind is that of Short. In fact, though epilepsy appears to have sometimes originated from some small tumor of this nature, or from a nervous cicatrix, and that Lassus has been enabled to cite Hippocrates, Galen, Celsus, and Alexander of Tralles in support of this, we find in none of these authors an example so conclusive as that of the English Physician. A woman affected with epilepsy for twelve years had up to that time had the paroxysms only once a month ; but they now began to appear four or five times a day, and to continue for an hour or an hour and a half. As they began always with a pain at the lower and inner side of the calf, Short examined the leg of the patient during one of these paroxysms. Plunging in a scalpel to about two inches in depth, he felt a small body which he separated from the muscles and excised. It was a hard cartilaginous mass, or sort of ganglion, of the size of a pea, situated upon a nerve which the surgeon divided with the same stroke of the instrument. The patient, who was immediately relieved of her paroxysm, cried out that she was perfectly well, and never had an attack afterwards. The young girl mentioned by Morgagni, and in whom the pains were so acute that she would have cut off her foot herself had she not been prevented, was also very speedily cured by the removal of the tumor. The same occurred in the case of Petit, who also speaks of the intolerable pains. In the patient of Cheselden, who experienced a numbness only at certain times, but suffered acute pains upon the least shock, the operation was no less fortunate ; as it was also in the two women operated upon by Camper, the one treated by Hunter ; and the patients of Dubois, Siebold, M. Reiche, &c. Surgeons of the present day, therefore, who would decline an operation of this kind, would be censurable. There is every reason to believe for example, that a patient who after an amputation of the thigh, continued for two years to suffer the most excruciating pains, which he referred to the extremity of his foot, might have been relieved of his misery, if the species of swelling or tumor which had formed above a portion of a branch of the sciatic nerve which had been included in the ligation of the vessels, could have possibly been extirpated. (Portal, *Anat. Méd.*, t. IV., p. 289.) The case, mentioned by Portal, who

states that he saw the specimen at Montpellier in the museum of Lamorier, reminds me of an observation: those nervous sympathetic pains, which occasionally persist for so long a time, and which many who have been amputated refer to limbs which they no longer have—are they not imputable to the fact that nervous filaments have in reality been included in the ligature with the vessels? [See remarks on this subject in Vol. I., under *Bleeding*; and Vol. II., under *Nerves*.]

## ARTICLE I.—EXTIRPATION OF NEUROMAS IN GENERAL.

Neuromatic tumors, in relation to their cure by extirpation, present three varieties. Some are situated between the aponeuroses and the integuments, and others are found under the aponeuroses at a depth which ordinarily corresponds with the track of the nerves. If there are some which seem to be continuous with the nervous cords, there are others which appear to have no kind of connection with this description of organs.

### § I.—*Sub-Cutaneous Neuromas.*

Whether they be continuous or not with the nervous branches, sub-cutaneous neuromas should, nevertheless, be extirpated nearly in the same manner in all cases. An incision of sufficient length is first made upon a line with the tumor itself. After having thus divided the skin and cellular tissue, the surgeon secures the tumor with an erigne and causes it to be raised up by an assistant while he isolates its sides. With a stroke of the bistoury or scissors, he then immediately after detaches its upper portion, then the deep-seated surface, and then its lower extremity. In this manner he annihilates with the first cut of his bistoury, by separating the nodule from its nervous centres, those painful irradiations sometimes insupportable, which he would otherwise occasion before having terminated the operation. Prudence would require that a layer of cellulo-adipose tissue of sufficient thickness should be removed with the neuroma. Unless the tumor should have acquired an extreme volume, that of a small melon for example, as in the patient amputated by Louis, or that of Ant. Dubois, the simple incision ought to be sufficient. A neuroma which should equal the size of a pullet's egg, as in the two cases reported by Reiche, would in almost all cases exact nothing more. As these tumors are usually sufficient regular, their dissection generally is easy. The tissues moreover by which they are surrounded, being in the normal state, are placed in excellent conditions for immediate reunion. It is on such occasions therefore, if ever, that we should approximate as accurately as possible the flaps or borders of the wound, and attempt the cure by first intention. Having a regular point d'appui or sort of barrier or protecting plane in the aponeuroses or bones which are found underneath the integuments, the surgeon experiences no difficulty in effecting the exact coaptation of the two opposite walls or lips of the solution of continuity. If, however, these tumors should have required, either in consequence of their volume, their degenerescence or some

anomaly in their form, the formation of numerous flaps, or a cavernous wound, we must proceed in the manner mentioned in the article on *Lymphatic tumors*. In other respects the wound which is made by the extirpation of sub-cutaneous neuromas, is a simple wound, and is to be considered in no other point of view.

## § II.—*Deep-seated Neuromas.*

Whenever it becomes necessary in order to reach the neuroma, to divide the aponeuroses, the operation becomes manifestly more serious. The limits of the tumor being less perfectly ascertained, do not enable us at first to regulate the extent of the incisions with all the precision desirable. To detach a sub-cutaneous neuroma we scarcely ever are in danger of wounding any important artery; some veins only can then embarrass the surgeon. In sub-aponeurotic neuromas, on the contrary, we have to guard against enormous vessels, and the same organs as in the case of lymphatic tumors. The incision of the integuments being made, we again endeavor by means of the finger carried to the bottom of the opening, to identify the exact position and size of the tumor, in order, without arresting the operation, to enlarge the external wound should it be deemed necessary. Dividing afterwards the aponeurosis with free cuts from without inwards, should there be neither large sized arteries, veins, or nerves in the neighborhood; but on the contrary, by puncture at first, and from within outwards, and on a grooved sound, when we have to proceed with caution; the surgeon then stops to examine anew the precise seat of the neuroma. While an assistant keeps the lips of the solution of continuity properly held apart, he continues to divide the tissues with care, and layer by layer, until the tumor is laid bare. He then secures it with a hook and causes it to be drawn upon by a second assistant, in order to facilitate him in isolating its two sides either by dissection or enucleation. Before separating it above or below, it is necessary to know if it belongs to a small or large nerve. In the first case, in fact, there is no necessity of our having recourse to a minute dissection in order to detach it, and to isolate it from the nervous filaments which surround it. We may without danger cut freely and completely through its two extremities, since the interruption of the functions of such nervous filaments, cannot create any very great degree of disturbance in the uses of the part which sustains them. If on the contrary the nerve is important and voluminous, we should endeavor, unless the thing should seem wholly impossible, to disengage it from the tumor and to dissect and isolate from it the filaments sometimes dispersed through it, (*éparpillées*.) and do every thing in fact to preserve its continuity while removing the neuroma. If, however, as has happened in a great number of cases, the nerve and the tumor are perfectly confounded together, we should decide upon removing the part degenerated, taking care to commence the section at the upper part of the tumor in order that the remainder of the operation may not be made more painful. In this manner it has been found practicable to remove one or two inches of the ulnar, radial or median nerve, without any very serious accidents, or permanent paralysis resulting therefrom. The

tumor being removed, whatever be the process, we must proceed to the ligature or torsion of the arteries, the arrestation of the hemorrhage by the known means, and the treatment of the wound in the manner described under operations in general; not forgetting that even under these circumstances the attempt at immediate reunion presents numerous chances of success. Nevertheless as we have here the supple and lamellar cellular tissue which separates the muscles, to transport inflammation and suppuration to distant points, we should not be too anxious for the immediate closure of the wound, when we find it impracticable to keep the different portions of it in the most exact coaptation possible.

## ARTICLE II.—EXTIRPATION OF NEUROMAS IN PARTICULAR.

### § I.—*Superficial Neuromas.*

Whatever be the region in which they exist, sub-cutaneous neuro-matic tumors are to be extirpated by a process which is the same every where, and for which the rules above given will be found sufficient.

A. *At the sole of the Foot.*—The limb being flexed and turned upon its outer side, I made an incision opposite the neuroma of an inch in length and parallel to the axis of the limb; having secured this tumor with an erigne, I glided underneath it the point of a straight bistoury, and readily separated it from the neighboring tissues, first behind and then in front. No arterial branch being opened, I was enabled to close the wound immediately, and to keep it thus united by a circular strip of adhesive plaster. The cure was accomplished at the end of a week.

B. *On the internal malleolus*, and on the whole antero-internal side of the leg we are to proceed, and would succeed in the same manner.

C. On the *knee* and in the neighborhood of the patella the limb should be extended or flexed, according as the tumor is more or less movable; but we must not turn it upon its outer side. After having laid bare and removed the tumor and united the wound, the limb should be placed also at the ham in a state of moderate flexion upon a pillow or large cushion.

D. For the anterior, inner, or outer side of the *thigh*, we should proceed in the same manner, without any necessity of more serious precautions after the operation. If the tumor was situated upon the outer or posterior region either of the leg or thigh, the surgeon would find some advantage in making his patient lie upon his belly. Nevertheless the incision of the skin, the excision of the neuroma, and the dressing, would be as in the preceding cases; and for the rest we should take care not to let the limb press upon the diseased region.

E. Neuromas of the *hand* or *fore-arm* are to be removed after the same rules. In all cases the limb should be placed so that the tumor should present itself in front of the operator, and in all cases also the wound could be united by means of strips of adhesive plaster or any other bandage. In the case of Neumann the tumor which had

existed for more than thirty years, was situated upon the lower and middle part of the fore-arm. After having divided the skin, it became necessary to tie several arterial branches, though the neuroma was only the size of a pea, and appeared to occupy a branch of the cutaneous nerve. It is difficult, however, to understand why Neumann was fearful of proceeding any farther, or that he should have thought it advisable to confine himself to narcotics and afterwards caustics to complete the operation. I have already said moreover, that the patient, who was seventy years of age, died of apoplexy before being cured of his wound. If, as in one of the cases of Camper, the neuroma should be situated outside of the elbow, and on the track of some of the branches of the musculo-cutaneous nerve, we should after having separated the limb from the trunk, keep it in a state of moderate extension during the whole course of the operation. It is important here that we should guard against the synovial capsule, and not penetrate deeper than is indispensably necessary in the direction of the articulation.

F. Upon the continuity of the arm, we should also have to turn the limb inwards or outwards upon its axis, according as the neuroma was placed more on one side than the other, and we should also have to guard against wounding the basilic or cephalic veins and the sub-aponeurotic organs. The thoracic limbs moreover, are those in which the dressing is most simple, and where the wound would have the best chance of cicatrizing by the first intention.

## § II.—*Deep-seated Neuromas.*

A. *The Thoracic Limbs.*—The extirpation of deep-seated neuromatic tumors has already been performed upon a great number of different regions.

I. I do not know if it has been employed upon the fore-arm. In all such cases we should have to divide the integuments and isolate the tumor in this region, in the same way as for cutting down upon the radial, ulnar or median nerve. In the case of Cheselden it is clearly perceived that the tumor occupied the middle of the *ulnar nerve*; but it is not mentioned if it was in the arm or fore-arm. Having separated the muscles apart and isolated the tumor, it would be necessary to detach the nerve from the artery before completing its double section. The *median nerve* being nearly at an equal distance from the two principal arteries of this region, might, so far as regards any immediate danger in the manipulation, be excised with less apprehension.

II. In the *arm* the neuroma may occupy the radial, ulnar or median nerve, or the cutaneous nerves. a. E. Home says that the tumor extirpated by Hunter, in a woman aged 20 years, was situated upon the *musculo-cutaneous nerve*; having laid bare the neuroma by a proper incision, he excised about three inches of the nerve. The loss of sensibility, which at first showed itself in the thumb and forefinger, did not long continue, and the patient was completely re-established. A woman, upon whom I operated in 1838 at the hospital of La Charité, had at the middle of the left arm in the substance of the biceps, a small ovoid movable tumor with painful irradiations, which had existed for a great number of years, and produced the symptoms

which usually attend neuromas. Having separated the arm from the trunk, I made an incision of two inches between the lower extremity of the deltoid and the origin of the supinator longus muscle. Dividing the tissues, layer by layer, I arrived at the fibres of the biceps muscle without touching the cephalic vein, and then reached the tumor, which I secured with an erigne, and then excised. The acute pain which the woman experienced every time I touched this neuroma, the greyish looking stem which was prolonged above and below, and the numbness of the entire outer side of the fore-arm after the operation, sufficiently prove, as I think, that the tumor in reality occupied the trunk of the musculo-cutaneous nerve. The wound was united by first intention, and except for a diffused erysipelas which spread from an issue which the woman carried in her arm, the cure would have been completed at the expiration of a week.

b. Upon the large nervous trunks the operation might be much more dangerous. The neuroma of the size of a melon, which according to Dubois, occupied the *median nerve* of the right arm, required the crucial incision, and the excision of a considerable portion of the nerve. The cure was accomplished, but the sides of the fingers remained insensible. It does not appear that Petit was under the necessity of making use of a complex incision for the removal of that neuromatic tumor of the size of a pullet's egg, which had existed for seven years in the arm of a young girl. As it was suspended, according to the author, to a small nervous cord, we may consider that it was situated upon one of the cutaneous nerves.

c. In the first case of Reiche, it was evidently situated upon the ulnar nerve. The surgeon, after having taken up a fold of the integuments, divided them to the extent of five inches. The dissection of the tumor obliged him to divide many small branches of arteries, without, however, occasioning any serious hemorrhage. It became necessary to remove with it about four inches of the nerve. The pains, which were very violent at first, afterwards diminished and changed in their nature, and were soon followed by a numbness in the hand. The wound was cicatrized in fifteen days, and nothing ensued from the operation but a slight degree of insensibility in the little finger. We should operate here, therefore, in the same way as for cutting down to, and tying the brachial artery, with this difference, that we are guided by the tumor, and that while raising up this last during the dissection, it is generally easy to reach the nerve and to excise it, by commencing in the direction towards its root.

d. In the hollow of the axilla, neuromas may also have their seat over the aponeuroses. E. Home, who had to cut down upon one of this kind contiguous to the great axillary nerve, says, without designating the process he adopted, that he effected its excision, and that the operation caused neither any great degree of pain, nor any other unpleasant symptom as its immediate consequence; but he adds, that a violent inflammation soon supervened in the region occupied by the tumor, and that it occasioned the death of the patient on the eighth day. The arm in these cases must be held wide apart from the chest, and the tissues are to be divided after the rules laid down for a ligature upon the axillary artery, rather than after those for the extirpation of lymphatic tumors. Neuromas, in fact, will be found to

be resting against the root of the arm, instead of tending, like degenerate lymphatic ganglions, to glue themselves against the thoracic wall of the axilla. The best means of avoiding the misfortune mentioned by Home, in such cases, would be to dress the wound with small balls of lint, in place of immediately attempting its union by first intention.

B. *The Abdominal Limb.*—I. Every thing goes to show that there is no deep-seated nerve of the *leg* which is exempt from neuromas. Up to the present time, however, the extirpation of these tumors at the foot and upon the whole length of the abdominal member, has scarcely been spoken of except under the title of sub-cutaneous tumors. The case of Short is almost the only one which would appear to coincide with a profound neuroma. Here no doubt can exist, for the author says he plunged in his scalpel to the depth of about two inches, and that he was obliged to separate the tumor from the muscles before extracting it with the forceps. We should have to be guided, moreover, by the precise situation of the tumor and the known track of the nerves of this region.

II. It is not known whether the neuromas of the *knee* or in the neighborhood of the patella, extirpated by Camper and A. Dubois, were rather sub-aponeurotic than sub-cutaneous; but the natural arrangement of the tissues of this region, induces rather to the opinion that they were in reality superficial tumors.

III. Though it might appear that the tumors extracted from the thigh by Loyseau, were situated between the aponeurosis and integuments, it is at least certain that in one of the patients whom I have already spoken of, and who had them on different parts of the body, the disease had its seat underneath (au-dessous) the fascia lata.

IV. This patient having died, we had an opportunity of practising upon the dead body the operation that might have been performed upon him during life. One of the tumors which was situated upon the antero-external lower third of the thigh, was laid bare by an incision two and a half inches long. Having reached below the aponeurosis, I had still to isolate it from among the fibres of the triceps muscle. There it appeared to form an immense spindle-shaped ganglion, of the size of a nut, upon the continuity of one of the branches of the crural nerve. A similar tumor located in the upper third of the limb, was situated underneath the sartorius, and would have rendered necessary the division of a part of this muscle.

V. *The sciatic nerve.* The most remarkable neuroma I have seen, was situated upon the posterior part of the thigh, at four fingers' breadth below the breech. The tumor, which had existed for many years, and had developed itself without any known cause, in a lady aged thirty years and upwards, was of the size of the head of a newborn infant. Assisted by M. Gorsse, the physician of the patient, I extirpated it in the following manner. Being placed upon her belly, with a pillow under the trunk, Mlle. H. was held in this position, while the leg was kept extended by other assistants. Having made an incision in the integuments parallel to the axis of the trunk, and six inches in length and commencing at the outer border of the ischium, I had to cut through the sub-cutaneous fascia, the fascia lata and sundry adipose layers before perceiving the tumor. Having

isolated it on its posterior surface, it was secured with a hook and drawn backwards, while I detached it on its inner and outer side by means of a careful and delicate dissection. I disengaged it in this manner from the long portion of the biceps, which was pushed inwards with the semi-tendinosus and semi-membranosus. It was not until then that it became evident that the sciatic nerve supported the whole of this mass, of which it formed as it were the axis. The fear of inducing gangrene, or at least an incurable paralysis of the limb, by excising a nerve of this volume, caused me to hesitate an instant. Seeing however that the tumor was perfectly free at the middle of the great cellular track, (*trainée*), which extends from the ischium to the ham, I asked myself the question, if it might not be possible to divest it of the nervous filaments and to remove it alone. After having therefore detached its whole circumference and dissected the nerve, first above and then below, as for an anatomical preparation, I recognized that there was nearly a third of it intact, or as it were enchased merely upon the anterior plane of the neuroma. The two other thirds of its cords were dispersed in the manner of the grill-work (*rayons*) of a cage or oyster pannier upon the two sides of the tumor. Encouraged by the extreme fortitude of the patient, I proceeded to isolate each one of those filaments by means of the bistoury, and succeeded in disengaging nearly the whole of them while pushing them towards their common centre in front. The neuroma thus removed left a cavity as large as the two fists, which I first filled up with small balls of lint, and then treated by secondary immediate reunion. The cicatrization of the wound appeared complete at the end of five weeks. An evident numbness and partial paralysis of the outer half of the foot and of the neighborhood of the corresponding malleolus, were the only accidents calculated to give me any uneasiness during the first week or two after this serious operation; but these symptoms subsided by degrees, and the cure, which was completed at the expiration of three months, remained permanent. It was in 1834 that the operation was performed. Mademoiselle H. married, and at the present time (December, 1838) is in the enjoyment of perfect health. Messrs. Roux and Chelius have each published a similar case, except that in the patient of M. Roux the tumor, which was of a cancerous nature, reappeared and terminated in death.

VI. I am not aware that other physicians have spoken of neuromas in the neck; for myself, however, I have every reason to believe that the tumor mentioned by M. Bérard, senior, and which I have spoken of under the article on *Excision of the nerves*, was one of this kind. I will add that in a dead body dissected by M. A. Thierry, I ascertained the existence of a spindle-shaped tumor of the size of a small pullet's egg, and of a reddish tint, on the middle of the continuity of the great sympathetic nerve at its cervical portion. It seemed as if this tumor might be a nervous ganglion excessively hypertrophied, and as it was no more adherent than normal nervous ganglions, it would have been evidently practicable to have cut down upon and extracted it, had it during life caused any serious symptoms. Proceeding in the same manner as for a ligature upon the carotid artery, it might have been removed without difficulty; and I do not think

the excision of a portion of the great sympathetic in a case of this kind, could be followed by any very formidable disturbance in the animal economy.

VII. Upon the thorax I have in four instances removed neuromatic tumors. Madame de T. for many years suffered neuralgic pains in the right side of her chest. A little tumor of the size and form of an almond, which had been noticed by M. Rayer, and which appeared to be the source of her sufferings, was situated between the 10th and 11th ribs, precisely at the place where the cincture of the gown is worn. To reach it, I was obliged by means of an incision of two inches, to divide the integuments, the sub-cutaneous fascia, some fibres of the latissimus dorsi and obliquus externus muscle, and afterwards the fibro-cellular layer which covers the external intercostals. Being hooked fast to and raised up by an erigne, the tumor caused a violent paroxysm of pain, and as it prolonged itself in front and backwards by a yellowish stem, it presented to me completely the appearance of a nervous ganglion. Having excised it posteriorly and then in front, I found there was no artery to tie, and drew the lips of the wound together by two strips of adhesive plaster, which I covered with a pledget of lint and body bandage. Some slight suppuration ensued, but the cure was nevertheless completed after the expiration of a short time. In the following year, that is, in the month of March, 1837, I was obliged to subject Madame de T. to a similar operation. A new neuroma had shown itself at an inch below and behind the first; the operation and its results were the same, and the patient has, up to the present time, (December, 1838,) remained free from any new trouble from this source. A young girl of 19 to 20 years of age, whom I operated upon at the hospital of La Charité in 1836, had at the same place, but upon the left side, a trilobate tumor of the size of a large nut, and which also presented the characters of neuroma. In this case an incision of three inches was required, and the tumor was almost entirely sub-cutaneous. Having dissected and removed it, I was nevertheless not enabled to close the wound by first intention, and the cure was not effected until at the expiration of five weeks. Another neuroma which I also met with on the thorax of a woman, was likewise situated at the same height. Are the constriction or frictions made there by the cord of the petticoat or the cincture of the frock, the cause in these cases? The case of the man which I have already several times alluded to, and who had so many neuromas dispersed over the chest and limbs, had one also between the cartilaginous border of the tenth rib and the umbilical region. In order not to be incommoded by the natural depression of the side, I laid bare the tumor in this case by means of a transverse incision slightly convex below. It became necessary therefore to cut through the skin, sub-cutaneous fascia and externus oblique muscle, for the tumor was situated quite deep. The extirpation was not in other respects difficult, but it required a ligature upon two arterial branches and left a sufficiently extensive cavity underneath the integuments. This patient, though cured of the operation, having a cancerous affection of the bones of the left wrist, underwent at a later period amputation of the fore-arm, which terminated in death at the expiration of twenty

days in consequence of numerous metastatic abscesses in the viscera and an enormous effusion in the pleura.

VIII. *Recapitulation*.—Neuromas (as we thus perceive being ordinarily uniform and perfectly isolated in the midst of the other tissues, may be extirpated without great difficulty in almost all patients. If they occupy small nerves it would be a useless precaution to endeavor to detach them from these, rather than to excise the nerve and the tumor at the same stroke. In the contrary case and especially if the sciatic nerve were involved, we should do our utmost to detach the nervous filaments from it, at least in part, as I succeeded in doing in the case mentioned farther back. If this separation were utterly impossible and the accidents caused by the neuroma were really serious, we should still finish the operation, at the risk of interrupting the continuity of a large nerve. The facts which I have related under the article on *Excision of nerves*, and those which have been considered in this chapter, prove that the consequences of such an operation rarely compromise the life, that they do not always alter the functions of the limb to an incurable extent, and that very frequently in fact the phenomena of sensation and motion which had been believed to be permanently destroyed, are ultimately more or less perfectly re-established.

## CHAPTER V.

### LIPOMAS, OR FATTY (Graisseuses) TUMORS OR WENS (Loupes).

Ever since surgeons, aided by the light of analysis, have sought to distinguish tumors rather by their nature than their form, the word *wen* (loupe) which was employed at first to designate all tumors, is scarcely ever used any longer except for such as are composed entirely of fat, which are the only ones recognized at the present time under the name of *lipoma* (lipome). After the example of some modern pathologists, therefore, I would understand by the word *loupe* or *lipoma*, which was invented by Littre (*Hist. de l'Acad. des Sc.*, 1709), tumors constituted of pure or degenerate fat. This species of disease which belongs to the class of hypertrophies, involves no danger in itself, and in reality incommodes only by its volume or weight, or the deformity it produces. Nevertheless lipomas appear to me to be susceptible of many kinds of transformation or decomposition. It is not impossible perhaps that they may undergo even cancerous degeneration; the putrescent transmutation (*la fonte putride*), however, is one of their most usual terminations. As on the other hand, however, these tumors scarcely ever disappear by resolution, and as their augmentation has no determinate limit, surgery must necessarily interpose its aid and devise means of disembarassing patients of them. The remedies adapted to them are reduced to a small number, and topical applications of whatever description are devoid of efficacy. General remedies would be more dangerous than useful.

There is nothing in fact in such cases, if we wish to do any thing effectual, but the mechanical or chemical destruction of the tumor that can be resorted to; so that the entire therapeutic of lipomas definitively resolves itself into this principle: that is, to destroy them by caustics, the ligature or the cutting instrument, or to do nothing at all. So long as the lipoma possesses little volume, is imperfectly defined, or scarcely causes any inconvenience, or is deeply situated, we may, if there is reason to believe that its increase will not ultimately render its destruction more dangerous, wait and do nothing, or confine ourselves to some hygienic precautions. On the contrary, whenever the lipoma is superficial, well-defined and easily accessible to an operation, it is much better to attack them at once than to temporize. Though it should even be unfavorably situated, we ought to advise the patient to get rid of it in good season, inasmuch as the operation, the longer it is delayed, since it must ultimately become indispensable, presents so much the less chance of success, in proportion as the tumor is of older date or more voluminous. On this point I will take the liberty of making a remark.

Fatty tumors are far from being situated always in the sub-cutaneous tissue, as most modern pathologists maintain. Without mentioning those which are seen in the chest, abdomen and pelvis, they are sufficiently often met with also, underneath the aponeuroses and even in the central portion of the limbs. It is easy to comprehend also that lipomas may exist wherever the adipose cells are naturally intermingled with the other tissues; so that we ought to have reason to be astonished rather at their absence than their presence between the muscular layers and bundles (*faisceaux*). There are, therefore, under this point of view, two classes of lipomas: the *sub-cutaneous* or superficial, and the *sub-aponeurotic* or deep-seated, in the same way also as there are two kinds of neuromas and two orders of lymphatic tumors. In respect to regions for which they have a predilection, it would be difficult to specify them; for fatty tumors have been observed upon almost every part of the body. I have met with them on the supra-hyoid region, on the cheeks and forehead and in the supra-clavicular region, upon the shoulder, at the middle of the arm, on the anterior border of the axilla, in front of the sternum or abdomen, at the nape, on the back, in the fold of the groin, at the perineum and upon the thighs and legs. Dupuytren (*Journ. Hebd. Universel*, t. IV., p. 28.) speaks of a lipoma which occupied the lumbar region. Dorsey (*Elements of Surgery &c.*, *Journ. des Progrès* t. IX., p. 281.) mentions the case of a lipoma which was situated upon the dorsal region, where I have also seen them in two instances. In the patient of M. Graefe (*Gaz. Méd.*, 1835, p. 169.) the tumor was situated between the muscles of the abdomen; and below the clavicle in the case of M. Portulapi (*Bulletin de Férussac*, t. I., p. 240. The *Lancet*, April, 1824, p. 24.) In a patient mentioned by M. Taramelli, the lipoma extended from the groin to the perineum (*Bull. de Férussac*, t. XVI., p. 85.); while that extirpated by M. Taillefer (*Gaz. Méd.*, 1837, p. 93.) was situated in the dorsal region. M. Serre (*Ibid.*, 1838, p. 266.) has seen one at the posterior region of the neck and M. Syme (*Edinb. Med. and Surg. Journ.*, vol. 137, p. 381.) met with a curious example of one in the hollow of the axilla.

Thus, as I shall describe farther on, I have encountered enormous fatty tumors in the posterior region and depth of the thigh, upon the acromion, on the arm, at the side, under the axilla, &c.; so that there is nothing more variable than lipomatous tumors, both as regards their form, depth or volume, or the region where they are situated. We may consult on this subject, Chopart, Louis, M. S. Cooper, Alibert and M. Pautrier (*Thèse* No. 6, Paris, 1834.) There is scarcely any other mode of curing lipomas except by the ligature or extirpation. Though the red-hot iron or caustics, properly so called, might be applied without any very great danger to sub-cutaneous lipomas, it would be a different case with those that are deep-seated. It is moreover a kind of remedy which is not suitable to lipomas that are greatly developed, and one which in no case deserves the preference over the two other operations which I have just mentioned.

The ligature for lipomas, sometimes sufficient, rarely preferable, and never indispensable, would not be conveniently applicable but to those which were pediculated or not of large volume. It should be applied, moreover, with the same precautions and by the same processes as for cutaneous and erectile tumors. It would also be applicable for fatty tumors, as for all others, to strangulate their roots after having dissected them, if there should be any great difficulty experienced in avoiding the deep-seated vessels; but their extirpation is, in truth, the best, and I might say, almost the only resource. In cases of sub-cutaneous lipoma, nothing is so simple as this operation. If the tumor is but of little volume, a straight smooth (unique) incision is first made through the integuments, either a T, or crucial, or semilunar, or a V, or L, or an ellipse, or even stellated, if any advantages are to result from it. As the tumor contains no liquid, there is no danger in wounding its tissue while cutting through the skin. As these tumors do not usually contract any intimate adhesions with the neighboring tissues, they are generally easily isolated and detached from the surrounding cellular texture; though even some pelotons should be left behind, the cure would not on that account be materially interfered with; and as they receive no large-sized vessel, they may be extirpated without incurring the risk of any serious hemorrhage. The teguments with which they are surrounded being scarcely ever diseased, may be preserved, reversed, and then approximated in such manner, after the operation, as to be brought into contact at every point. The bottom and flaps of the wound being almost constantly composed of sound tissues, surprisingly facilitate all the efforts at immediate union or primitive agglutination.

The extirpation of lipomas is thus one of those operations which are performed with the least repugnance, and undertaken with the greatest degree of confidence. Nevertheless, it would be wrong to decide upon it on too slight grounds. An adult man, strong, and of good constitution, and about fifty years of age, came to the hospital of Saint Louis, in 1822, for the removal of a lipoma of the size of the two fists, and situated upon the postero-superior part of the right shoulder. The extirpation of this tumor, which was performed by M. Richerand, presented at first nothing peculiar. But an erysipelas, which ultimately extended from the shoulder to the nape, and from the neck to the cranium, soon put a period to his life. An old

man who had a lipoma, larger in volume than the head of an adult, appended as it were to the posterior region of the neck, operated upon by M. Roux, in 1825, at the hospital of the Faculty, also perished in a few days. When, therefore, we decide upon extirpating lipomas, it is important to guard against the general consequences of operations, in the same way as in the extirpation of all other sorts of tumors.

#### ARTICLE I.—SUB-CUTANEOUS LIPOMAS.

The arrangement of the incisions and the character of the operative process, ought moreover, in general, to vary, according to the size, form, and seat of the tumor. M. Gensoul (Pautrier, *Thèse* No. 6, Paris, 1834,) who, like MM. Rust, Walther and Textor (*Rust's Hand. der Chir.*, t. VI., p. 683), first plunges a long knife through the root of the tumor to separate it, first on one side and then on the other, has the advantage of terminating the operation rapidly; but he runs the risk of sacrificing useful integuments and cutting out irregular flaps. It is better therefore to make use of the bistoury, and to divide the skin from without inwards, and to prepare flaps of suitable form and extent, to be well adapted to, and to cover over, the wound accurately after the removal of the tumor. Fabre (*Observ. de Chir.*, in-12, 1778) after having laid them bare by a longitudinal incision, and passed a ribbon through their base in the same direction, so as to enable him to draw them towards him, recommends that we should strangle their root by a ligature, which being tightened gradually during the dissection, has the advantage of pushing out (*chasser*) the tumor and benumbing the pain; but it is doubtful if this process, which is not every where practicable, finds many partisans at the present day. Complex incisions also are not indispensable but for lipomas of a certain size. By means of a straight incision I was enabled to remove from the root of the shoulder a lipoma of larger size than a pullet's egg. Nevertheless, if the integuments should be too much attenuated, the tumor approach the size of the fist or exceed it, or the skin have undergone the least degenerescence, it would be preferable to have recourse to complex incisions, and even to sacrifice a portion of the integuments, rather than rely upon a simple incision.

#### § I.

A young girl from the country, whom M. Rayer desired me to operate upon in his wards, at La Charité, had in front and below the left clavicle a trilobate lipoma, of the size of the fist. After having first made an incision through the tissues from the neighborhood of the sternum to the root of the shoulder, I then divided the skin from above downwards to the extent of two inches, making thus two triangular flaps, which were dissected and reversed, the one outwards and the other inwards. After the removal of the tumor these two flaps were readily raised up to the horizontal branch of the T and adapted to the bottom of the wound by means of strips of adhesive plaster.

## § II.

A man aged from 45 to 50 years, who had in the supra-clavicular depression a lipoma, which a charlatan, by means of different caustics, had transformed into a bleeding fungus, was received, in 1837, into the hospital of La Charité for the purpose of having his tumor removed. The integuments in this case being destroyed or degenerated, I was obliged to surround the lipoma with two curved incisions, and to remove with it an ellipse of the skin and of the celluloadipose sub-cutaneous tissue. An erysipelas supervened, but the patient, nevertheless, got well in a short time, as also did the young girl whom I have just spoken of.

## § III.

A woman of more than usual embonpoint, had between the lower border of the axilla and the side of the thorax a badly-defined lump of the size of an egg, which caused her, she said, acute suffering. For the removal of this tumor, which was continuous and without *any line of demarcation*, with the general adipose tissue, I required only a simple incision three inches in length, and parallel to the lower border of the pectoralis major near the chest.

## § IV.

Another woman from 35 to 36 years of age and whom M. Ribail had sent to me, had in front of the acromion and on the anterior surface of the right deltoid muscle, a lipoma, slightly flattened, lumpy (*bosselé*), and of the volume of a pullet's egg. I was enabled to remove this also by the straight incision, and the cure was not interfered with by any serious accident. A young girl who was sent to me by Doctor C. Piron, had a lipoma of the same size as the preceding on the acromial side of the left shoulder. Here the adhesions were such that I considered it proper to lay it bare by means of a T incision, whose stem was turned backwards and slightly outward. This patient was also cured.

## § V.

In the case of the young man mentioned farther back, and who had a slightly elongated fatty tumor of the size of the fist, below the lower jaw, I was equally obliged to recur to the T incision; nor did any inconvenience result from it, and the patient soon recovered. There is every reason to believe, however, that a semilunar incision, with its free border below, would have permitted me, by raising up by dissection the flap of soft parts thus circumscribed, to complete the operation with as much certainty and security.

## § VI.

Having to remove a lumpy (*bosselée*) lipomatous tumor of the size of a small egg, and of very irregular form, on the left side of the waist of a woman who was admitted into the hospital of La Charité in 1837, I limited myself to a simple incision of three inches in length, and parallel to the direction of the neighboring rib. Immediate reunion took place, and the patient was well in a few days, and without any suppuration. Recently, on the 18th of December,

1838, I removed a similar tumor which a student of medicine had upon his right side. I made a vertical incision slightly convex posteriorly, and in five days after the young man was cured. These examples, I presume, are sufficient to point out the different modes of extirpating superficial lipomas of moderate volume.

### § VII.

But if the tumor should be of a larger size, we must proceed in another manner, always, however, in conformity with the anatomical requirements of the region, or of the part where they are situated. If the ancients had given more details of their experience, we should probably have had evidence of large-sized lipomas having been noticed by them. That horrible tumor of the size of the head, and which subsided and increased, and hung near the ear of a baker, mentioned by Felix Plater, (Bonet, *Corps de Méd.*, t. III., p. 14,) was it not a fatty tumor? The one called steatomatous by Lotichius, (Bonet, t. IV., p. 322,) which was also of the size of a man's head, and likewise situated behind the ear, evidently belonged to the class of lipomas. We see also by a case of M. Serre (*Gaz. Méd.*, 1838, p. 266,) that fatty tumors upon the posterior region of the neck may acquire an enormous volume, and a weight of at least seven pounds. The one I noticed in 1825, and which occupied the same region, was not less voluminous than the steatoma mentioned by Lotichius or by F. Plater. It appears that M. Miller even had extirpated one of the weight of twenty pounds, and which M. Warren (*Surg. Observ. on Tumors*, p. 55,) was enabled to show entire to his pupils. Whatever may be the volume, lipomas of the posterior region, of the neck or ears, are nevertheless extirpated nearly in the same manner as superficial fatty tumors in general. While almost constantly sub-cutaneous in these regions, they have scarcely much greater breadth to their root when very voluminous than when they are in the condition of small lipomas. But the danger of their extirpation lies in the depth of their root, and in the thickness of their pedicle, much more than in the totality of their mass. There is nothing to avoid there but the occipital artery or the auriculo-mastoidean above, and some branches of the cervical arteries below. The patient operated upon by M. Serre recovered perfectly well, and there is nothing to induce us to think that the operation should be more dangerous here than anywhere else. A steatoma of the size of the head, which was situated upon the occipital region of a child two and a half years old, was removed by M. Seerig with perfect success, (*Arch. Gén. de Méd.*, 3e série, t. I., p. 115,) while F. de Hilden, (Bonet, p. 83,) on the authority of a letter of Scretta, speaks also of a child two months old, and which was operated upon in this manner at the hospital of Strasburg, for an enormous tumor which it had on its nape.

### § VIII.

The posterior region of the trunk also has frequently presented these enormous lipomas. The alleged sarcoma of such prodigious size which formed between the shoulders in a woman mentioned by F. Plater, (Bonet, t. III., p. 14,) and which was successfully removed, was probably a degenerate lipoma. Dupuytren removed one of

these, which was partitioned off with several osseous plates, and which was situated above the lumbar region, in a woman aged sixty years. Dorsey (*Journ. des Progrès*, t. IX., p. 280,) states that he removed from the back of a man a lipoma which weighed twenty-five pounds. The cure took place rapidly, and the figure given by the author shows that this tumor held on to the trunk only by a sort of fold of the integuments. A friend of A. Petit, (*Anat. Chir. de Palfin*, t. II., p. 19,) by making use of the ligature, was enabled to separate from the dorsal region, a lipoma of twenty-eight pounds, and another of forty-eight pounds. A patient, seen by Petit himself, had one upon the back, which *must* have weighed at least sixty pounds. A lipoma in the same region, of four pounds' weight, was since extirpated by M. Taillefer, (*Gaz. Méd.*, 1837, p. 93,) who united the wound by suture, and cured his patient in fifteen days; so that on this plane of the trunk the extirpation of fatty tumors presents numerous chances of success, whatever may be their volume and weight.

## ARTICLE II.—SUB-APONEUROTIC LIPOMAS.

### § I.

Though lipomas may exist on the anterior region of the body, the remark, nevertheless, is true, that they are less frequently developed there than behind. The largest sized one I have noticed on the sternum did not exceed the dimensions of the fist. There is no proof to show that the tumor shaped like a ball, of the size of a man's head, and which was situated in the substance of the parietes of the abdomen, as mentioned by F. Plater (Bonet, t. III., p. 15), was a fatty tumor, rather than one of any other kind.

### § II.

That which M. Graefe (*Gaz. Méd.*, 1835, p. 169,) extirpated under the title of lipoma, and which was situated below the obliquus externus, was it in reality a fatty tumor? It is readily conceivable, moreover, that the operation would not be sensibly more difficult in front of the chest than in the dorsal region. But in the abdomen the case would be different if the tumor really had its seat underneath the muscles or aponeuroses. The risk of wounding the epigastric, internal mammary, lumbar or intercostal arteries, would here be among the least of the inconveniences to encounter from the operation. It is the neighborhood of the peritoneum and the development of inflammations and of consecutive suppurations, which would then be the real sources of danger.

### § III.

The same dangers would exist if the lipomas were developed in the sides or hypochondriac regions. Lotichius (Bonet, t. IV, p. 321,) states that he saw in the hypochondrium of a patient, a steatoma of the size of the head, and that the extirpation of this tumor undertaken by a charlatan, was followed by death at the end of two days. F. Plater (*Ibid.*, t. III., p. 15,) also speaks of a tumor which had a strong resemblance to the brain, and which existed in a young man, on the left side, near the back; but no one had the courage to undertake its

removal. That case of a *carcinoma*, also, which occupied the right hypochondrium, was of the size of a child's head, and extirpated with success, and the history of which is given by Bartholin, (Bonet, t. IV, p. 461,) was it not, perhaps, a degenerated lipoma? M. Warren (*on Tumors*, p. 57,) has extirpated a lipomatous tumor above the side and hypochondrium, and which was situated between the ribs and the lower portion of the serratus magnus.

#### § IV.

Be that as it may, it is in the vicinity of the root of the limbs and upon the limbs themselves, or on the thorax, that the largest sized lipomas have been noticed. I do not speak here of the man whom M. Sédillot showed me, and who had the whole circumference of his neck surrounded by an enormous collar-shaped (*bourrelet*) indolent, lumpy [*bosselée*] tumor, because I am no more certain that this was of a fatty character, than I am that that was in the child mentioned by M. Warren, (*Ibid.*, pl. 14, p. 428.) Another patient whom M. Lebatard sent to me in 1838, had the whole of the neck imprisoned, as it were, in enormous masses of a lipomatous appearance, at the same time that similar tumors existed in the axilla and groins; but neither here, also, am I certain that they were legitimate lipomas.

#### § V.

In the region of the *shoulder* they have been noticed above, in front, behind and outside. The patient operated upon successfully in 1823, by M. Portulapi, had a lipoma of fifty-two pounds' weight, the root of which was situated in the subclavicular fossa. Already this surgeon, in 1814, had removed another lipoma weighing fourteen pounds. Dupuytren (*Archiv. Gén. de Méd.*, t. V, p. 430,) removed one weighing six pounds, situated on the posterior part of the shoulder of a patient, who recovered; and I have, as I have said, observed many others of a certain size, which were situated also upon the stump of the shoulder, properly so called.

Though in the supra-clavicular depression, lipomas rarely acquire an extreme volume, they present here at least some particular features in connection with their extirpation, and dangers and difficulties which it is important not to be ignorant of. Those which are subcutaneous demand no further attention there than elsewhere. It is when they are situated beneath the aponeurosis, that their diagnosis and removal may be difficult. The softness of the neighboring tissues, the void which the hollow of the axilla opens to them in front and upon the outside, and the subscapular cavity behind, admit of their being depressed and flattened with extreme facility, and of projecting or disappearing, so to speak, in the manner of a congestive abscess (*abcès par congestion*) or varicose tumors, and of appearing soft like a hernia or abscess, or conveying the idea of a disease altogether different. I had a woman for several months at La Charité in 1838, who carried a lipoma of this kind in the left supra-clavicular depression, and who in this manner became the subject of very different opinions on the part of those who had an opportunity of examining her. Another patient whom I operated upon with M.

Maingault, had a tumor in the same region, whose size did not appear to exceed that of a pullet's egg. An incision extending from the outer border of the sterno-mastoid muscle, to the apex of the acromion in the direction of the omo-hyoideus muscle, enabled us, after having divided through the integuments and aponeurosis, to lay the tumor bare. In order to isolate it, it became necessary to divide many branches of the cervical plexus. Having arrived below the clavicle in front, and upon the anterior side of the border of the scapula behind, we recognized that this tumor, which seemed so accurately defined at first, prolonged itself into the hollow of the axilla, where it became necessary to penetrate the whole depth of my finger to detach it by enucleation from below upwards, from among the nervous cords which compose the brachial plexus. I removed in this manner, by a laborious and tedious dissection, a completely fatty mass of very irregular shape, and of the size of the fist. We left in its place an enormous cavity, which was filled with small balls of lint, and which ultimately cicatrized so perfectly and in so simple a manner, that the patient was enabled to return from Paris to Rouen at the expiration of a month.

## § VI.

It is rare that lipomas acquire in the arm or fore-arm, sufficient size to require our attention to be called to them as tumors of a remarkable character. The thoracic limb properly so called, is in fact one of the regions of the body where fatty tumors are the least frequently observed. Upon the supposition that the species of steatoma which was situated underneath the skin of the fore-arm in a patient mentioned by M. Galenzowski, (*Journ. des Progrès*, t. VIII., p. 221,) was a lipomatous mass, rather than a tumor of some other description—this at least would be an exception; for I repeat that lipomas of the upper extremity rarely exceed the size of an egg, and it would be difficult if not impossible to cite a series of examples where they originated underneath the aponeurosis. Fabre (*Observ. de Chir.*, in-12, p. 51,) however gives a remarkable instance of one. The tumor was monstrous. Extending from the apex of the deltoid to the external condyle of the humerus, it was prolonged transversely under the cephalic vein, then between the brachialis internus and biceps muscles, continuously with the external aponeurotic intersection of the arm.

## § VII.

The *thigh* on the contrary has often been invaded by this description of tumors, and it is there especially that we encounter them of a remarkable size. M. Taramelli (*Bulletin de Férussac*, t. XVI., p. 85) states that he successfully extirpated a lipoma weighing eight pounds, which reached from the root of the fold of the groin to the perineum. A tumor which weighed eighteen pounds, and whose root ascended into the pelvis at the perineum, and which M. Kohlrusch (*Ibid.*, t. XII., p. 232) who describes it as a steatoma, succeeded in removing so as to cure his patient, was evidently also of a lipomatous character. M. Benedict, (*Bull. de Férussac*, t. I., p. 239,) in fact relates, that he

extirpated from the thigh a fatty tumor, caused by a fire-arm, and in which he found some pieces of money ! In 1838, I removed from the outer and lower part of the thigh, in a woman 40 years of age, a fatty tumor of the size of the head ! This lipoma, which had existed for years, and which might have been taken for an encephaloid tumor, required an incision of ten inches in length in the direction of the vastus externus muscle, and another much shorter, transversely in the direction of the ham. The dissection discovered to us, that this mass, in place of penetrating beneath the aponeurosis in the ham, had simply depressed the fascia lata in the direction of the gastrocnemii muscles between the tendons of the biceps and semi-tendinosus, and then in the external supra-condyloid groove of the knee. No accident supervened, and the cure, which has remained perfect up to the present time, (January, 1838,) confirms what the dissection moreover had authorized us to believe, that the tumor in question was a lipoma, and not a cerebriform tumor.

### § VIII.

Also it is the same with lipomas of the thigh and leg, as with lipomas in every other region of the body ; whatever may be their volume, their extirpation is generally attended with but little danger when they do not go beyond the depth of the sub-cutaneous layer. It is no longer so however, when their root is situated among the muscles. In such cases the patient cannot be relieved of them but by means of a dangerous operation ; the more so as fatty tumors of this description readily acquire a very large size. There was one of this kind at the hospital of Saint-Louis, in 1837, the size of which was equal to two adult heads. In a patient mentioned by M. Klein, (*Graefe und Walther Journ.*, vol. I. p. 112,) the lipoma reached from the breech to the ham, and weighed near 28 pounds. A woman who was admitted into the hospital of La Charité in 1836 had a similar tumor in the same region ; and in 1837 I operated for another which weighed 32 pounds in a man from the country, who had also a lipoma of the size of a child's head in the dorsal region. Fatty tumors therefore constitute in this region an extremely serious disease. Originating among the muscles, in the midst of pliant tissues, they ordinarily acquire great dimensions in their vertical diameter, before becoming prominent under the skin. In the woman I have spoken of, the tumor, which descended down to between the gastrocnemii muscles, and ascended nearly as high as the attachment of the gluteus maximus, and had extensively separated the muscles and vessels, and was eighteen inches long and eight to ten in thickness, nevertheless weighed only from eight to nine pounds. The one I removed in 1837, and which occupied precisely the same region, ascended about five inches higher than the first and descended only to three or four inches below the knee. Though it weighed 32 pounds and was of enormous volume, as the cast of it in wax which was deposited in the museum of the Faculty shows, yet it had not deformed the substance of the thigh to a much greater depth than that of which I have just spoken. The patient operated upon by M. Klein and in whom the tumor singularly resembled in its situation, nature and weight, that of

the patient on whom I myself operated, died on the ninth day, while mine succumbed on the eighth. The woman, on the contrary, whom I have mentioned first, ultimately recovered; when at the end of three months and after having experienced several attacks of erysipelas, she left the hospital, she continued to walk for a long time in the wards, and the wound had completely cicatrized. When called upon to such tumors, the surgeon ought to put to himself a number of questions. Knowing that the patient cannot be relieved of the difficulty without endangering loss of life, he ought first to ask himself if it is proper to meddle with the case. Should the tumor incommode only by its weight and volume, and had not undergone any degeneration, and had developed itself very slowly and made no further progress, perhaps it would be more prudent to respect it especially in a person in advanced age or dyspeptic (*cacochyme*.) In the contrary case we have no resource but extirpation of the tumor or amputation of the limb, as the dimensions of the pedicle no longer admit of the employment of the ligature and as caustics are inadmissible in any case. Amputation of the thigh for a lipoma has something in it strange and repugnant. It is true that in order to remove these enormous tumors, we may be obliged to divide a certain number of the posterior muscles of this part of the limb; that the continuity of the femoral vessels and of the sciatic nerve, run some risk of being implicated, and that in every case we are more or less compelled to create an enormous wound, whose suppuration is necessarily exceedingly dangerous. But besides that most of the muscles, from being simply spread out or widened apart, may if necessary be avoided, the lobes of the lipomatous tumors are ordinarily sufficiently movable to allow of their being readily enucleated from the periphery of the vessels and nerves. Moreover, the division of the femoral artery or sciatic nerve, would it necessarily result in gangrene and death? It is not to be forgotten that amputation in such cases is to be performed either in the articulation itself or very near the great trochanter, and that besides the slight prospect of success it presents, there would nevertheless, even under the most favorable circumstances possible, be thereby produced an immense amount of mutilation; while the pure and simple extirpation of the tumor, which in the aggregate would not be more dangerous than the extirpation of the limb, would at least have the advantage, should it succeed, of effectually curing the patient. I would not therefore prefer amputation of the thigh to extirpation of the tumor, unless it should be found impossible to operate without wounding at the same time the crural artery and nerve as well as the sciatic nerve. Of the two patients I operated upon, one it is true died, but he had been exhausted by long-suffering and was near sixty years of age; the other however recovered, though the dissection in her during the operation had been almost as extensive as in the other.

The extirpation of these lipomas, however, in this region, is more frightful or dangerous than really difficult: to accomplish it I adopted two different modes. In the first case I made an incision which went directly down to the adipose tissue, and extended from the tuberosity of the ischium along the semi-tendinosus muscle as far down as below the ham. Transforming this first into a T incision, I

divided the tissues outwardly as far as to the external side of the triceps muscle. Having reversed the two flaps of the T, I had only to divide the two thirds of the long portion of the biceps. Then dissecting the tumor with free strokes of the instrument, I detached it first on its outer side, then inwards and then from above downwards, either by means of the bistoury, or with the fingers or the handle of the scalpel, completing the extirpation in less than five minutes. In the second patient the mass was so immense, and furrowed by veins so numerous and so enlarged, that I deemed it proper to remove with it a large ellipse of integuments. I was obliged in this manner to include in the incision a portion of the biceps muscle, and of the semi-tendinosus, semi-membranosus and gracilis muscles, which were broadly spread out in the manner of a membrane, upon the surface of the lipoma. Having detached this gigantic tumor from the external parts of the leg and thigh, I tore out a lobe from it from below the breech, and then a second from the hollow of the ham; but from its having enveloped the vessels in its extension inwards, the dissection on this part became difficult and laborious. The great anastomosing artery, which I could not avoid at the distance of two lines only from the trunk of the crural, made me fear at first that I had wounded this last. The isolation of the sciatic nerve also was not unattended with difficulty. The operation nevertheless, notwithstanding the rupture of two or three putrescent (putrilagineuses) cavities which I had to empty as I proceeded, was neither very long nor very laborious; it did not last over a quarter of an hour. In neither case did the approximation of the lips of the wound present any difficulty. But for the attacks of erysipelas and some menaces of purulent infection which supervened in the woman operated upon in 1836, accidents which may be developed after an operation of the least serious nature, the cure certainly would not have required more than five or six weeks to be accomplished. In the man who perished, and upon whom I did not operate until after having taken the advice of MM. Ribes, Larrey, Marjolin, Sanson, Laugier, Bérard the elder, Bérard the younger, Monod, Robert and all the other distinguished surgeons of Paris, death appeared to have been the result of defect of reaction, and as it were exhaustion of the vital principle. These operations, however, up to the present time have not been performed sufficiently often, to enable us to appreciate with exactitude their value or their danger.

### § IX.

I would remark in conclusion, that lipomas, like lymphatic tumors and neuromas, are so easily detached from the surrounding tissues, that enucleation is applicable to them, and ought to be substituted to the employment of the bistoury, wherever there would be danger of wounding the large vessels or important nerves. Being situated independently, and as it were without any organic attachment, in the midst of the tissues, they may moreover be torn out without fear by means of the finger or any other mode. They are the kind of tumors in fine whose extirpation, all other things being equal, involves the fewest dangers, and presents the best chances for success.

together with the greatest degree of facility and simplicity in the operative manual.

[*Fatty Tumors*.—Our countryman, Dr. Parker, a missionary in China, has had much practical experience in a peculiar form of enormous *cutaneous or fatty tumors*, which he has seen or operated for successfully during his philanthropic labors. In a recent memoir of his, published in Cormack's *Monthly Journal of Med. Science*, (June, 1846, p. 393, &c.) he mentions one in a beggar aged 35 on the right side of his face, and which increased in ten years to two and a half feet in circumference. Dr. Parker extirpated it without difficulty by two elliptical incisions, each eighteen inches long. It weighed near nine pounds, and was of glandular structure, with a few cells containing a yellow or dark fluid, and was in part cartilaginous. A slight paralysis only was left from the division of the portio dura. The patient recovered so well in three weeks as to perform the duties of porter to the missionary hospital. These excessive growths of a lipomatous or with mixed cartilaginous and encysted organization, and which in some cases have been seen by Dr. Parker (according to the paintings he exhibited at New York,) to extend *like wings* from the whole posterior portion of the trunk and lower limb on one side, appear to be the result of the excessive indulgence or gluttony in the Chinese for farinaceous and other non-nitrogenized kinds of food, that favor fatty growths and accumulations. See note on Mr. McIlvalne's views on this subject, Vol. II.]

---

## CHAPTER VI.

### ELEPHANTINE TUMORS.

The class of elephantine tumors, very common in Africa, the Indias, and many countries of Asia and America, but rare in Europe, and especially in France, are met with only as an exception in other than the genital organs either of men or women. Being caused by an hypertrophy, together with degenerescence of the integuments, or cellular tissue, and sometimes of the aponeuroses and muscles, they may acquire a development still more considerable than lipomas. I have seen instances of them upon the nose, ears, feet and hands, and some other regions of the body. In 1836, at the hospital of La Charité, a woman was brought to me, of about forty years of age, who had the hand, fore-arm and elbow three times their natural size, in consequence of a degenerescence of this kind, and in whom the upper half of the arm, as well as all the other parts of the body were in a perfectly sound condition; so that the disease had become suddenly arrested at the distance of two or three inches above the humero-cubital articulation. A man in whom I extirpated the limb at the articulation, and to whose case I have elsewhere alluded, had upon his right arm a similar degenerescence, which extended from the extremities of the fingers to the shoulder, and ultimately became

complicated with a cancerous or colloid transformation at the centre of the humerus. I have met with many instances of persons who had in this manner the foot and the leg, either partially or wholly enlarged to double, triple, or even quadruple their natural size. In one of these patients the elephantine tumor abruptly terminated in the form of an enormous lardaceous collar, at some inches below the knee. In the greater part of them the disease imperceptibly disappeared above, and in all of them the limb truly exhibited the appearance of the leg of an elephant. Should the tumor be accurately defined, as in the case of those I have been describing, and should it have been of long standing and have resisted all the means indicated by a judicious therapeutic, we may, should the person be in other respects in good health, propose its removal. But in such cases it is amputation of the limb itself only, which presents any chances of success, or that can be had recourse to. In all cases, on the contrary, where the elephantine degeneration shall appear to be imperfectly limited or prolonged under the form of indurated plates or radiations beyond the tumor itself, properly so called; or complicated with plates or projections of a similar nature, on other parts of the body; or we have reason to suspect the slightest alteration in the viscera; or that the health of the patient has been profoundly deteriorated, we must be cautious not to meddle with it, or confine ourselves to palliatives. I shall, however, return to these tumors in speaking of operations performed on each region of the body, in particular, and especially upon the scrotum or vulva. The tumors called keloid, (*keloides*) which I have seen in the form of a firm, reddish-colored lardaceous plate, four to six lines in thickness, and two inches in breadth, upon the shoulder of a young lady, who had already been operated upon for it, by M. Forget; which I have met with also, under the angle of the scapula, in the dorsal region of another female; and which M. Warren, (*on Tumors*, etc., p. 45, pl. 3,) who has described them, appears also to have observed on the shoulder; should be destroyed by means of the zinc paste, or extirpated with the same precautions as if they were of the character of an erectile or elephantine tumor. Extirpation would be applicable only to the *eloid* (*eloides*) tumors described by the same author (*Ibid.*, p. 48, pl. 4), and which show themselves under the form of a bunch of agglomerated enormous-sized leeches, or of a small intestine coiled up upon a circumscribed point of the skin.

[M. Colson, of Noyon (France), describes (see *Journ. des Connaiss. &c.*, de Paris, Mai, 1842, p. 189 et seq.) a remarkable case of African elephantiasis in a woman who died at the age of 53, after fifty years of suffering from that and the antecedent diseases which appear to have led to its production. The privations of poverty, impoverished diet and constant residence in a marshy situation (commune of Salency) predisposed doubtless to this train of maladies, which commenced in infancy after small pox with a large tumor on the right side of the vulva, which after some years' continuance was destroyed by an empiric by means of caustic. The right side of the abdomen and thigh however began to swell before her catamenia appeared, when another empiric attacked these parts with the cautery and caustics, applying these remedies both above and below the

knee, the last of which caused erysipelas and gangrene of the leg, and denudation of the tibia. This last wound partially recovered, but continued an open, discharging ulcer for many years—the hypertrophy of the thigh also gradually increasing. Worms were engendered in these foul ulcers. At the age of 38 this wound healed, and ulcers were established at the malleoli. The menses were most of the time regular, but the urine was occasionally suppressed, which latter difficulty was relieved by nitrate of potash drinks, bringing on copious evacuations of this secretion, which sometimes had a milky appearance. The thigh at the middle part was over thirty-seven inches in circumference, covered on the posterior part, as was also the dorsum of the foot, with thick, offensive incrustations, also in various parts with tubercles (as is common in tropical elephantiasis), while the leg of the diseased limb was also hypertrophied in its lower part to the dimensions of over twenty-one inches in circumference, having enormous red vegetations about the ankles—the whole limb being at least three times the size of the other. It retained to some extent the powers of flexion and extension. T.

## CHAPTER VII.

### HEMATIC TUMORS.

A kind of tumors whose pathology might constitute several species, and which had scarcely been noticed before I described them in 1826, and afterwards in 1833, are those which are caused by effusions of blood. These tumors which have a predilection for the synovial bursæ, and which sometimes form for themselves cysts in the cellular tissue, are either solid, fluid, or semi-fluid, or sometimes constituted of a melange of concrete clots with matters that are altogether of a fluid nature. I shall, when speaking of cysts (kystes), return to those which contain rather fluid than concrete matters; at present I shall confine myself to solid hematic tumors. These tumors perhaps are more common than would at first be thought. I have elsewhere remarked (*Traité des Contusions*, Paris, 1833), that certain polypi of the uterus, some tumors of the prostate, with steatomas of the head, breast, &c., often appeared to me to owe their origin to an effusion of blood or fibrinous concretion, and numerous facts have since confirmed me in this opinion. This much, however, is certain, that most of the tumors described under the title of steatoma or lipoma, and which do not belong to the order of fatty tumors, enter into the category of hematic tumors. The tumor of 188 grammes in weight, which a patient carried for the space of twenty years upon the right side of his head, under the denomination of a lipoma, and which was successfully extirpated by M. D. Lasserre (*Cas de Chir.*, pp. 21, 22, 23, Perigueux, 1833) was to all appearance nothing more than a degenerate hematic tumor. The same was the case as I should think, with another tumor of the size of an egg, situated below the mamma to the left on the thorax of a man, and

which the same practitioner removed; also with that which existed upon the shoulder and which he also extirpated; the same with a cyst filled with matter resembling boiled rice and situated upon the left cheek of a man; and with the cyst still larger, which a woman had on her knee, together with some other tumors, for which M. D. Lassarve in like manner operated. Hematic tumors differ from lipomas in general, in this, that they are scarcely ever pediculated; that they rarely exceed the size of an egg, the fist or the head; that they are almost constantly surrounded with an irregular cyst when they are situated in the cellular tissue, but sufficiently regular, on the contrary, when they are formed in the bursæ mucosæ or the synovial cavities; in this also, that the matter of which they are composed, is either clotty or fibrinous or fibrous, and of a variable color, yellowish, gray, sandy (rousse) or brownish; and that serous or synovial matter is frequently found mingled with it. Like lipomas, hematic tumors do not usually cause any pain, and incommode in reality only by their volume or weight. Like lipomas also, and perhaps more frequently than them, they appear to be susceptible of degenerating and undergoing transformations of a bad character. No topical application or internal medication can destroy them when they are of old date or have acquired a certain volume. Caustics, the ligature and extirpation, therefore, are the only remedies we have at our command.

## ARTICLE I.—HEMATIC TUMORS IN GENERAL.

### § I.

*Plasters*, liquids and all kinds of discutient (fondants) topical applications, by which we sometimes succeed in obtaining resolution of sanguineous deposits, have no longer any efficacy when we have under treatment an ancient hematic concrete tumor. These means, eulogized by M. Champion, as irritating injections have been by M. Asselin, (*Considérations sur les Bourses Muqueuses*, Strasbourg, 1803,) possess in reality no value except in recent hematic tumors.

### § II.

*Caustics*, besides their inconvenience of destroying integuments which it might be advantageous to preserve, would also be attended with the objection of exacting a considerable space of time, and of failing in the majority of cases. A surgeon mentioned by Lombard, (*Opuscules de Chirurgie*, p. 108, 1786,) who wished to destroy at every possible hazard a tumor evidently hematic, in front of the knee, by means of caustics, could not effect his object, but caused by this means several abscesses in the neighborhood of the patella. At most, therefore, escharotics under such circumstances, could only be employed in association with the ligature, as was practised by F. Aquapendente and has been since done by Chopart and Sabatier; or in the case of those persons who peremptorily refuse every other kind of operation.

## § III.

The *ligature* upon hematic tumors is still more uncertain than for lipomas. As these tumors almost always present a very large base, and have besides a more or less distinct cyst, they are badly adapted to constrictive means, and do not find in such resources their best remedy.

## § IV.

It is to *extirpation* therefore that we must have recourse, if we wish to relieve the patient. The question might then be asked, if it would not be sufficient to lay open and empty the cyst? To this first question we may reply, that the simple incision, which would doubtless sometimes succeed, would most frequently prove unsuccessful, expose to more accidents than extirpation, and render the remainder of the operation obviously more difficult. If Paroisse (*Opusculs de Chir.* etc., p. 94, 1806,) was enabled to extract a cyst of this kind by a simple incision, it was because inflammation, excited in the cyst by an irritating injection, had previously isolated it from the surrounding tissues. All that we can demand in such cases is, to know if it is indispensable to carry away the totality of the cyst with the tumor, or limit ourselves to the excision of the latter. Sainct Christeau, (*La Chirurgie Pratique*, p. 180, 1697,) having restricted himself to emptying a steatoma of the size of the fist, which was situated upon the inner side of the thigh, found himself obliged to scarify the internal surface of the sac, and to dress the cavity with an exciting digestive before he could effect its cicatrization.

## § V.

*Excision*, properly so called, is of such doubtful efficacy, that J. Fabrice, (*Œuvr. Compl.*, partie 2, p. 620,) was already aware of it, and in his time recommends that we should divide the vessel which nourishes the remains of the cyst. This mode, however, has been since lauded, first by Chopart and also by Louis, or by Percy, (*Dict. des Sc. Méd.*, t. XXVII., p. 44, 45,) but it is to Mosnier, (*Thèse*, Paris, an XI.) and to Bourdet, (*Essais sur les Loupes*, p. 23,) that it is specially indebted for having been rescued from oblivion, and been made to assume a kind of celebrity at the commencement of the present century. Mosnier pretends that after this operation, the bottom of the wound is transformed into cicatrices, and takes the place of integuments. The facts, nevertheless, advanced by those observers, and which are applicable at most to certain regions of the body, have not been of a character to convince any one, or to be received as laws, and extirpation, properly so called, has continued to be generally preferred. Perhaps, however, we have gone too far in this respect, and that it would answer the purpose when the posterior wall of the cyst cannot be dissected without too much difficulty, that it should be left in its place and made to suppurate. We cannot see, in fact, and practice is nearly silent on this subject, why, after suppuration, the walls of a wound of this kind ought to have so much difficulty in agglutinating. Only in this case I would not recommend that the integuments should be removed with the tumor ;

at least we should preserve a sufficiency of them to enable us to cover the bottom of the wound. It is nevertheless true that this practice must be considered as an exception, and that unless there are particular objections, the extirpation of the entire hematic pouch ought to have the preference. The *operative process* also is sufficiently simple. If the tumor is very voluminous, we remove with it an ellipse or a star of the integuments. In the contrary case, we lay it bare by means of the simple incision, that of the T, or the crucial. Perhaps, in such cases, the semilunar would be preferable. The tumor being concrete, enables us to isolate its envelopes without fear, and at the same time to reverse the entire sub-cutaneous layer. This first dissection being terminated, an assistant is charged with holding the flaps of the integuments apart and of making traction upon the tumor in the proper direction, while the surgeon detaches and carefully isolates it with the strokes of his bistoury from the deep-seated parts. As the hematic tumors, which may be extirpated in this way, are almost always sub-cutaneous, their extirpation is scarcely ever accompanied with serious hemorrhage. There are therefore generally but a small number of ligatures to place on arteries to tie. If the totality of the cyst has been destroyed, and the wound reposes every where on pliant vascular tissues, and the flaps have been cut of proper shape, there is a prospect of success by immediate reunion, and it ought to be attempted. Under opposite circumstances it is better to dress at first with the balls of lint, over which the flaps are to be brought, and which in their turn are to be covered with a perforated linen, plumasseaux, compresses and the simple containing bandage, until the wound has become completely cleansed and the flaps undergone all their retraction. By this means we avoid the danger of nervous accidents, purulent collections, and erysipelas, but we must be prepared to find the wound cicatrize slowly, and the patient not thoroughly cured until after the expiration of one or two months.

## ARTICLE II.—HEMATIC TUMORS IN PARTICULAR.

Hematic tumors may develop themselves upon all the regions of the body. It is rare however, except in the superficial or deep-seated mucous bursæ, that they are distinguished, as respects the operation, from lymphatic tumors or neuromas, since everywhere else their extirpation is subjected to the same rules for the operative process that those last named tumors are.

### § I.

Were it necessary to describe the process for extirpating hematic tumors in all those regions where synovial bursæ exist, I should have to examine those of the temporo-maxillary region, chin, angle of the jaw, the thyroid angle, spinous process of the seventh vertebra, the dorsal and lumbar region, that of the ribs and sternum, the lower angle of the scapula, the acromion, inner condyle of the humerus, the radius, ulna, metacarpo-phalangeal angles, both dorsal and palmar, the phalangeal articulations, the spine of the ilium, the great trochanter, condyles of the femur, spine of the tibia, head of the fibula, the malleoli, heel, tarsus, first and fifth bones of the metatarsus, club

feet, those with feet amputated, who are humpbacked &c.; but there are in reality no others but that of the knee and perhaps that of the malleoli, which require in this respect particular mention.

## § II.

I have in three instances extirpated hematic tumors which were situated in the mucous bursæ of the *malleoli*, in that of the outer ankle in two cases, and in that of the inner in the third. In such cases, if it is the external malleolus, we must be on our guard against opening into the sheath of the tendons of the peroneus longus and brevis muscles behind, and wounding the synovial cavity of the tibio-tarsal articulation below. The danger also of purulent inflammation in a region of this description, ought to deter us here from attempting union by the first intention, if the state of the wound or nature of the flaps do not appear to be favorable to it. At the internal malleolus we must be on our guard against wounding the sheath of the tibialis anticus muscle and the posterior tibial artery behind, and the articulation and the sheath of the tibialis anticus muscle below and in front.

## § III.—*Hematic Tumors of the Knee.*

In no place are the tumors of which I am speaking more frequently encountered than about the knee, and especially in front of the patella; nor is there any region perhaps, where their extirpation exposes to as much danger. A tumor of the size of two fists, which was situated upon the left knee, and which M. Hip. Larrey (*Gaz. Méd.*, 1838, p. 712,) gives as an example of hematic tumor, was extirpated at the Hospital of Val-de-Grâce. The officer who was the subject of it was soon seized with general accidents and with delirium, followed by death on the eighth day. Two patients operated upon for simple tumors, one by M. Roux, the other by myself in 1825, at the hospital of Perfectionnement, died in the same way and in as short a space of time. M. Hervez de Chegoin (*Journ. Hebd. Univ.*, t. III., p. 329,) who still gives the name of *lipoma* to these tumors, and who confesses that he does not comprehend their character, has sometimes practised their extirpation with success, but he is far from dissembling also the gravity of the operation. Extirpation performed by M. Warren (*on Tumors*, etc. p. 40) for a cancerous tumor in front of the patella, was also followed by death. It is sufficiently remarkable also that death in these cases should have resulted from cerebral phenomena and ataxic symptoms, which are scarcely explicable by the local accidents occasioned by the wound itself. I hasten to add, however, that in the great majority of cases, the operation is not followed by any unpleasant symptoms, but most usually in fact, effects a complete and sufficiently rapid cure. Six of the patients whom I have treated in this manner recovered perfectly.

*Operative Process.*—The patient is to be placed upon his back and his leg maintained in a moderate state of extension; one assistant takes charge of the foot and the other of the thigh. If the tumor has but little volume, the surgeon lays it bare by means of a longitudinal incision. In the contrary case, and where the skin is to be

preserved entire, I prefer the semilunar incision, taking care to turn its free border outwards. If the simple incision has been used, its two lips are dissected in succession, and reversed as far as to the borders of the patella. With the semilunar incision we carefully detach the flap of the integuments from without inwardly, and in such manner as to reverse it upon its base upon the inner side of the knee.

If on account of any particular reasons, we should consider ourselves obliged to give the preference to the crucial incision, we must detach and reverse its four flaps upon their base, with the same care. The same remark applies to the elliptical or to the stellated incision, with this difference only, that we should here leave a portion of integument on the apex of the tumor. In whatever manner performed, the tegumentary envelopes having been turned back, we proceed to the isolation of the periphery and deep-seated surface of the cyst. All the precautions required for this dissection, have reference to the articulation of the knee and to the diseased cyst itself, there being no large sized artery or nerve found in the neighborhood. We must therefore not forget that upon the outside, and both above and below the patella, the synovial cavity might be readily opened, and that the same remark applies to the inner side; but that directly in front there is nothing in this respect to be apprehended. In no other region also do hematic tumors exact more attention in regard to the extirpation of their cyst. However little there may remain of its posterior wall at the bottom of the wound, this cyst retards and even prevents cicatrization, and keeps up a suppuration whose consequences are not always devoid of danger. A patient whom I found at the hospital of Saint Antoine in 1828, and whom Beauchêne had operated upon two months before, retained a large purulent cavity in front of the knee. The posterior wall of the cyst left at the bottom of wound, had taken on all the characters of fibro-mucous lamellæ of a new formation, and exhibited no disposition to improve (*à la mondification*). I adopted the plan of removing it by a careful dissection, and from that moment the wound cicatrized regularly and without any difficulty. It is necessary therefore, in these extirpations, to follow exactly the line which separates the natural tissues from the thick envelope of the tumor. Should some shreds of the cyst have at first escaped from under the bistoury, we must immediately after seize them with a double erigne or claw-forceps, (see Vol. I.) and extract them before terminating the operation. The dressing also deserves some attention. The flaps having no other support to rest upon than osseous or fibrous planes, or tissues that are but little vascular, and being moreover usually very thin, should not be brought over and maintained upon the wound except by means of a very moderate degree of traction and compression. All the pieces of dressing also which are to cover them, should be sufficiently pliant, and so lightly adjusted that no strangulation may be produced either in the direction of the leg or thigh. The leg also, by placing a thin cushion under the ham, should be kept in a state of gentle flexion rather than in complete extension. At the first sign of inflammation also, it would become imperative to envelop the knee in compresses or emollient cataplasms, and to cover it with leeches and renounce every attempt at immediate union. At

a later period, and when the borders of the wound have become agglutinated and united to the subjacent tissue, but are at some distance apart, it may on the other hand become useful to place the leg in extension, and to maintain it in that manner by means of an immovable dressing. Unless that is done, the slightest flexion of the knee brings the patella between the lips of the wound in the manner of a wedge, and may retard the cure to an indefinite period.

---

## CHAPTER VIII.

### CYSTS (Kystes) PROPERLY SO CALLED.

Cysts form one of the most numerous class of tumors, and have among them a sufficient number of varieties. Besides the purulent, hematic and synovial cysts, there are the melicerous, atheromatous, steatomatous and hydatid, and such as are purely serous, all of which sometimes reclaim the aid of surgery.

#### ARTICLE I.—SEBACEOUS CYSTS.

Quite a numerous order of cysts are those that are formed at the expense of the follicles of the skin. The tumors which result from them and which are generally known under the name of *maggots* (tannes, or *worms*) and *meliceris*, receive also other appellations when they exist in the form of pimples (boutons), rugosities or simple tubercles. They are frequently observed upon the scrotum and skin of the penis, and not exceeding in size a pin's head, yet susceptible of being made to yield by pressure a clot of sebaceous matter. On the face these little tumors when they inflame are called red pimples (couperose), causing very small abscesses, which are also relieved by strong pressure, after having perforated their apex with the point of a pin. But it is not with small cysts of this description that operative surgery has any particular connection. When the sebaceous matter is accumulated in greater quantity in the crypts, it distends and enlarges them to such degree as to produce tumors, whose dimensions vary from that of a pea to that of a pullet's egg. These tumors, which usually do not cause any pain, which are unattended with any inflammatory action or change in the color of the skin, and which possess a great regularity in their form, are soft (mollasses), slightly fungous and as it were semi-fluctuating. The cranium, face and neck are their most favorite localities. They are noticed also on other regions of the body. I have met with one upon the shoulder of the size of a pullet's egg; and also encountered them on the legs, thighs and fore-arms. Even the fingers themselves may be the seat of these tumors. A man in the country, whom I knew in my childhood, had upon the dorsal surface of the middle articulation of the left middle finger, one of these tumors which was of the size of a very large nut, in such manner as to form there an enormous mass which projected posteriorly. A patient of M. Fisher operated upon

by M. Warren (*on Tumors, &c.*, p. 529, pl. 16.) had one of a most singular description in front of the great trochanter. Some patients have several at the same time, and this peculiarity is principally seen where the sebaceous cysts are of but little size. It is proper however to say, that I have met with many of the largest kind at the same time upon the same individual

The following case perhaps also belongs to tumors of this description. An officer of health in the environs of Paris, a robust man aged 55 years, had for many years in the right supra-hyoid and parotid region, a tumor which ascended as high up as upon a line with the cheek bone and the labial opening of the mouth on the outer side of the jaw. This tumor, which when I had an opportunity of observing it in the spring of 1838, had already undergone various degrees of transformation, so much resembled an osteo-sarcoma that many experienced practitioners of the capital had characterized it as such; its extension towards the larynx below and the pharynx behind and in the direction of the mouth, had even precluded all idea of an operation, and confined the recommendations to the palliative treatment for cancerous affections. Under the impression that I recognized something fluctuating in its most prominent lumps (*bosselures*), and that there was also a certain mobility in the tumor, and that it presented neither the positive characters of cancer or evidence of actual adhesions with the maxillary bone, I considered it proper to lay it open freely upon one portion of it. I was enabled thereby to extract from it several ounces of a matter either melicerous, grumulous or semi-purulent, which resembled neither fibrine, pus nor tuberculous matter, nor fat or gelatine, nor the substance known as encephaloid, colloid or melanotic (*mélanique*), and which had in a word no analogy with any of the substances which are usually found in cysts.

Sebaceous matter was the only substance to which one could possibly in some respects compare it, that is to say, that this substance, unctuous in some portions of it and friable, and as it were desiccated in others, had for its receptacle a cavity whose walls singularly resembled in their papillar (*pointillé*) or cutaneous aspect that of melicerous cysts. Anxious to know what course to pursue, and wishing moreover not to influence his judgment, I confided a portion of this material to M. Donné that he might submit it to the microscope and certain chemical reagents, without having informed him of the intention I had in view. This physician, at the expiration of two days informed me, that he had found nothing but fatty matter and *particles* (*paillettes*) of *epiderm*, in the substance which I had transmitted to him, and consequently it could come only from a disease of the epiderm or of the follicles of the skin. Am I then right in concluding that the tumor in question was in reality of the description of that known as a maggot (*tanne*) and proceeding from a sebaceous cyst? Adopting the affirmative, I will add at the present time, that these cysts in breaking up (*se décomposant*) may undergo transformation of a bad character; for a patient whom I have since exhibited at the Clinique and who had a tumor of the same kind more advanced, and in the same region, was ultimately attacked with a legitimate cancer of the lower jaw. Be this as it may, melicerous cysts rebel against

all resources except those of operative surgery. When they have acquired a certain volume and remain in the chronic state, we may by compressing them upon their sides, or by dilating the little spot or black-colored hole (*pertuis*) which we generally succeed in finding on some one of the points of their periphery, and which is as it were their outlet, empty them and effect the discharge of matter resembling worms; but they are not cured by these means. The sac soon after fills up, and the tumor is not long in re-acquiring its primitive volume. It is from proceeding in this manner, that some have been induced to believe that the disease actually consisted of worms coiled up underneath the skin. The small black point which gets out first, is taken for the head of the worm, and the sebaceous matter which threads out in an undulating line as it comes through the cutaneous aperture, completes the illusion. This has proceeded to such extent, that having presented for examination, a thread of this kind of two inches in length which I had just extracted from a maggot ulcerated below the left breast of an adult man, the interne at first and the physician afterwards, assured me it was an entozootic worm and were preparing to designate its species, when I disabused them of their delusion. Topical applications, whatever be their nature, have no influence upon this kind of worm. The merely laying them open, or exciting inflammation in them by means of a seton, acupuncture, or needles or threads passed through them, does not hinder them from being reproduced. Even their excision in certain cases does not always cure the patient. They must either be extirpated completely, or after having emptied them by a large opening, carefully cauterized throughout their whole interior. The director of one of our royal theatres, had in front of the left temple a sebaceous cyst of the size of a large bean. As he did not wish to submit to any sort of bloody operation, I confined myself at first to the evacuation of the melicerous matter by enlarging a little the opening of the tumor. The latter having returned, I laid it open with a cut of the lancet and voided it again. But it again returned, and the patient at length consented to have it extirpated.

A physician who was a member of the Royal Academy of Medicine, had at the upper and posterior part of the right orbital angle, a sebaceous cyst of an inch in diameter. It was frequently laid open in order to empty it, but the tumor invariably reappeared; he decided upon having its whole cavity cauterized, and was thus cured. In the patient who had one of these cysts on the top of his shoulder, I excised all the projecting portion of it and touched the remainder with nitrate of silver. Hardly any inflammation ensued; the epidemic portion at the bottom of the wound sloughed off at the expiration of eight days; the borders of the wound were not approximated, and it was the preserved portion of the sebaceous cavity which served the place of the cicatrices, and assumed the appearance and most of the characters of cutaneous tissues. In conclusion, therefore, should the cyst not be of large size, the best plan is, after having circumscribed it in an ellipse by two semilunar incisions, to seize it with an erigne and extirpate it. If the approximation of the borders of the wound and immediate reunion should be interfered with by this mode of excision, we should commence with a straight incision, whose lips

should then be dissected and carefully separated on each side, leaving intact the tumor, which should be secured with a hook, and afterwards extirpated. By this mode the operation is longer, more difficult and more painful; besides which, notwithstanding all our precautions, we most usually cut into the cyst before having completed the dissection, because the thickness of its walls can scarcely ever be correctly ascertained beforehand, and moreover, are frequently found intimately blended with the skin.

A child three years of age, had upon the right external orbital angle and in front of the temporal fossa, a sebaceous cyst of an inch in diameter. As there was a dread of any kind of cicatrix, I laid it bare by means of a simple incision. I had already isolated two thirds of it, when a movement of the little patient caused me to cut into it in front. The tractions which I was constantly obliged to make upon it to get it out, had soon emptied it, and I perceived on terminating, that there was about a centime of it in breadth left at the bottom of the wound. I touched this portion of it freely with nitrate of silver, and the cure was effected perfectly. The wife of a distinguished magistrate of Paris had under her left ear, a sebaceous cyst, slightly elongated in shape, and of the size of a nut. Desirous of avoiding the slightest trace of a wound at this part, and at the same time to make the operation sure and prompt, I commenced by seizing the tumor with an erigne, which I confided to M. Prus, the physician the family, while M. Vasseur who also acted as my assistant, stretched the integuments. By means of two incisions slightly incurvated, I circumscribed a very long ellipse of integuments, which I removed with the tumor, and which enabled me readily to enucleate the latter in front and behind, and then from above downwards, by means of the bistoury. The lips of the wound were easily approximated and the cure completed in three days without any suppuration. If on the contrary the tumor should be very large, it would be better to lay it open freely, empty it with care, and then thoroughly cauterize its whole cavity. The same process also would be suitable for cysts that are less voluminous, if there were no great danger of a cicatrix slightly deformed. Finally, the excision, or rather the amputation of the tumor, together with cauterization of its deep-seated wall, would be applicable for those which have a large base, and which cannot be extirpated entire, or which we do not wish to submit to a simple incision aided by caustic. Upon the whole, we cannot cure sebaceous cysts but by extirpating them completely, or after having excised them, making use of their deep-seated wall as a portion of integument to serve as the cicatrix. As these are a kind of tumors, however, developed in the substance of the dermoid tissue, or in the appendices and cul-de-sacs of the skin, the operations employed for them are attended with very little danger, and rarely compromise the life. Owing to their superficial position it is next to impossible in operating upon them, to wound either arteries, veins, nerves, or any important organ. As these operations, except we extirpate, do not oblige us to go as deep as the sub-cutaneous fascia, it must be only in very rare cases that they can give rise to diffused phlegmon, phlegmonous erysipelas, phlebitis, or purulent infection. Erysipelas properly so called, angioleucite, and the unpleasantness of a cicatrix more or less de-

formed, together with the pain, are the only inconveniences that can occasionally result from them.

[In America, and especially in the West India or tropical portion of it, these diseased sebaceous follicles, wherever the heat of the climate and hot sun are constantly exciting the skin, are very common, and particularly upon the face from its great exposure, and in that part most frequent upon the dorsal surface of the extremity of the nose and upon its alæ. Their enlargement is unquestionably first greatly accelerated by the vulgar practice of squeezing out these so-called worms, so accurately described by our author. Intemperate persons, addicted also to gross indulgences in indigestible food, as crude fruits, fish, &c., and those most exposed to the hot sun in warm climates, as seafaring persons, seem most obnoxious to this hypertrophy. In the remarkable case (to which I find no parallel on record) which I operated upon in Nassau, the capital of the Bahama Islands in the year 1825, and which is inserted below, the cure was complete, and there was no attempt whatever made by me to save any integuments at all, as that was in fact impossible for the great breadth of base of each tumor, as is seen in the accurate accompanying sketches taken from life by myself. The diseased parts, however, were carefully and thoroughly shaved off *en dedolant* with the bistoury, while raised up with the forefinger in the nostril, until I reached the cartilages, leaving them in this manner, in fact the whole of the nose from above the limits of the tumor, perfectly *raw*. It is in fact surprising almost, considering the heat of the climate and weather, that gangrene did not take place. The man lived many years with his new and normal shaped nose, was the object of universal remark and reference, and ultimately died of some other disease.

TO DAVID HOSACK, M.D., F.R.S., PROFESSOR IN THE UNIVERSITY OF THE STATE OF NEW YORK.

*New York, Nov. 19, 1825.*

DEAR SIR,—Mr. John Russel, aged 54 years, a planter, of Abaco, one of the Bahama Islands, of robust short stature, and of sanguine temperament, was attacked in the year 1799 with small-pox, from which he recovered after a severe illness. His face remained much pitted, and the surface of the nose was particularly rough. Soon after, there was a perceptible enlargement of the teguments covering the anterior and lateral cartilages of the nose, which increased the more rapidly, as he imagined, from the practice of squeezing out of the end and sides of the nose what are vulgarly called worms, but which are well known to be the secretion of sebaceous glands, indurated and blackened externally by exposure to the air in the orifices of their excretory ducts.

Sir Astley Cooper has expressed an opinion that encysted tumors may arise from obstruction in the glandular follicles of the skin, and this may have been the first cause of the disease. It is not uncommon in the more remote and unfrequented, or what are called *out-islands* in the Bahamas, to meet with fatty tumors of small size and globular shape, upon the teguments of the forehead, nose, and cheek. I have heard them attributed, with plausibility, to the use of salt fish

and crude vegetable food. Nothing however like the gigantic growth of Russel's nose was ever seen in the West Indies, or any where described in the annals of surgery.

This patient came to consult me at Nassau, island of New Providence, about the middle of October, 1824.

For the last twenty years the nose had not varied materially from the extraordinary dimensions and grotesque appearance which the sketch presents in Plate I.

This enormous mass of disease consisted of three lobular tumors, having the appearance of a tribolate pendulous excrescence from the nose.

On examination I found them soft to the feel, and not only pitting, but exuding, on pressure, through minute and almost imperceptible pores, like those of a carbuncle, a thin, glairy, yellowish pus. For years, he informed me, he had been daily in the habit, during the warm weather, of squeezing out through these pores (which are doubtless the original orifices of the diseased sebaceous follicles) a teaspoonful or more of matter occasionally mixed with blood. They were so movable as to be easily turned up upon the forehead, so as to exhibit the openings into the nostrils underneath, which in their natural position, hanging down upon the mouth, they entirely concealed. The middle tumor extended down as far as the lower lip, upon which it rested, interfering very much with drinking and eating, and also with articulation. This, the largest of the three, was about *two inches* in breadth, and, measuring from the anterior to the posterior surface, an *inch and a half* in diameter: the lowest part of it incurvated over the nostrils. The shape was spherical, as also that of the two lateral tumors, which were more globate, and about *one inch* in diameter. Each lateral tumor was seated upon the external surface of the ala of the nose, leaving the rim of the inferior part of the ala in its natural state, but closely adhering to the cartilage above this by a broad base nearly co-extensive with the diameters of the tumors. The middle lobe, however, involved the whole of the tip of the nose, had a larger base and attachment than the lateral lobes, and was more firmly adherent than them to the cartilages upon which it was situated. The middle tumor was also entirely separated on each side from the lateral tumors by a deep fissure, leaving each tumor upon a distinct base. These fissures had been made deeper, he said, by constantly handling and wiping out the clammy matter secreted between the tumors. The teguments upon the diseased part were of the same flushed color and rough appearance as upon the rest of the face.

The remarkable tumors upon the nose of this patient had been familiarly known for years throughout the Bahamas, as well as in many parts of the West India islands; and so extraordinary and unique were they considered, that he was in his travels everywhere proverbially designated by the cognomen of *Big-Nose Russel*. The sneering and sarcastic observations many persons had unfeelingly made upon his misfortune, had for the last ten years, he told me, almost prevented him from going abroad.

There was no pain or irritability on handling the diseased mass, but the weight of it at night was so unpleasant as to inconvenience

his respiration, unless lying on his back ; in which posture, also, the nose interfering with the mouth, would cause him frequently to spring from bed during sleep, with a sense of strangulation. The weight may be imagined from the deep wrinkles upon the forehead and around the eyes, occasioned by the incessant and powerful action of the occipito-frontalis and adjoining muscles, in their effort to sustain the tumors.

After having proposed the operation to the patient, and with much difficulty made him understand that no serious consequences were to be apprehended from it, he went home to Abaco, and in a few weeks returned to Nassau, for the purpose of having it accomplished.

In the meanwhile, the proposition I had made became generally known ; and on his return to Nassau, most of his friends, and one or two practitioners of the place, secretly dissuaded him from it, and told him that an operation of such moment rendered it advisable that he should go to London, and consult Sir Astley Cooper or Mr. Abernethy.

These recommendations, the motives for which, in several of his advisers, it was by no means difficult to interpret, had the effect which was intended ; so much so that when, after he had been at Nassau several weeks, I again suggested the operation, he positively and unequivocally declined. I had almost despaired of again bringing his mind to the resolution of having the deformity removed, until at length, on Tuesday, November 23d, 1824, I succeeded in gaining his entire assent. The operation was performed about noon of that day, in presence of Mr. Brydon, Assistant Surgeon of the Forces at Nassau, in the following manner : passing the scalpel first on the outer edge of the left lateral tumor until it was removed smoothly from the cartilages to which it was attached, then doing the same with the right lateral tumor, and finishing in the same manner, with the middle lobe ; the whole operation being completed *in five minutes*. Several large compresses were then placed over the nose across the face, secured by a bandage round the head, to check the hæmorrhage, which was not more than eight ounces. Openings were made through the compresses to admit light to the eyes. In four days the dressings were removed, and in exactly *two weeks* from the moment of the operation, the wound having (under the carbon, bark, and alcohol poultice, and tonics internally) kindly granulated by the first intention, the patient, to the astonishment of an assembled multitude, who thronged after him, appeared at the public vendue with a *smooth, handsomely formed nose*. The chagrin which this spectacle occasioned to those who had endeavored to defeat the operation, may be much more easily imagined than described.

On passing an incision through the different tumors, they were found to consist entirely of a dense, homogeneous, adipose or fatty substance of a white color, each containing near its centre one or more small spherical cysts of about a quarter of an inch in diameter, filled with a thick, pappy, or a *theromatous* fluid of a yellow color.

Plate II. exhibits the appearance of the face and nose after the cure.

Yours, respectfully,

DR. HOSACK.

P. S. TOWNSEND.

From the account of the case as published by me at New York, 1825, p. 1 to p. 8, inclusive. T.]

three weeks after the operation.

## ARTICLE II.—HEMATIC CYSTS.

When the unabsorbed extravasations of blood do not give rise to concrete hematic tumors, they become perverted in their nature and result in the formation of cysts which contain sometimes a melange of fibrinous clots and of a more or less yellowish-colored, red or brown serum, and sometimes concretions which have been designated as free (*libres*, i. e. loose) cartilages, and as hydatid granules and lymphatic productions, which are found floating in the midst of a more or less abundant unctuous, lactescent or diaphanous liquid; so that the whole conveys the idea of grains of barley or rice as seen in a potage, or of cartilaginous or plastic plates or bodies, or laminae or septa, sometimes free, at other times adherent to the interior of the pouch. Nor is it rare to find the whole contents of the cysts transformed into a homogeneous liquid, sometimes of a reddish color and ropy (*sirupeux*), sometimes milky or rose-colored and of an unctuous feel, or at other times wholly serous or slightly lemon-colored.

§ I.—*Hematic Cysts in general.*

The various kinds of hematic cysts do not differ in any respect as regards the progress, duration or consequences of the tumor, but render certain remedies better adapted to some than to others.

A. Thus cysts that are purely liquid sometimes disappear under the use of *resolvent topical applications*, compresses saturated with a solution of sal ammoniac or iodine, frictions with mercurial ointment and that of hydriodate of potassa. Temporary blistering also succeeds quite frequently.

B. A remedy much more powerful than the preceding, and besides much more simple, consists in incising the cyst on some depending portion of it and emptying it completely. This being done, accurate methodical compression enables us to bring its walls into immediate contact and in this manner sometimes to obtain agglutination by the first intention. Otherwise it suffices to keep the incision open for four or five days by means of a *meche* (tent), that inflammation may be established within the cyst and render its agglutination almost unavoidable.

C. But the best remedy in such cases evidently consists in irritating injections, such as are employed in hydrocele. A puncture with the trochar empties the tumor without difficulty; immediately injecting through the canula of this instrument a certain quantity of tincture of iodine, in the proportion of a third of the tincture to two-thirds of water, I obtain a moderate inflammatory action, which causes but little pain and almost always terminates in the perfect cure of the cyst. Up to the present time I have not found that the tincture of iodine has produced any of those inflammatory accidents and purulent abscesses which some practitioners charge to vinous injections, eulogized, and also employed successfully a long time ago by M. Asselin, (*Thèse sur les Tumeurs des Bourses Muqueuses*, Strasbourg, 1803.) Hematic cysts therefore that are purely liquid, have no need in my opinion of excision, extirpation or caustics, and

the most they can require after resolvent topical remedies, temporary blisters, iodine injections and the simple incision, would be multiplied incisions. The cyst being well circumscribed, allows neither the liquid nor the inflammation, when the latter is moderate, from becoming infiltrated or diffused into the neighboring cellular tissue to such extent as to create the least uneasiness, while the disease may be compared in every respect to a hydrocele.

D. If in place of matters purely liquid, the cyst should contain a variety of the concrete clots which I have mentioned, there might be necessity for operations somewhat more complicated. Then, in fact, it is rare that the irritating injection and puncture, or simple incision, suffice. We might, however, make trial of one or the other of these operations, where the cyst reposes in every portion of it, in the midst of soft tissues. Emptied of the liquid matter it contains, the tumor, if afterwards submitted to compression and the action of discutient applications or temporary blisters, might possibly become concrete and transformed into a nodule that would ultimately disappear by simple resolution. In other cases, and where the cyst assumes most of the characters of synovial tissue, it would be illusory to count on the efficacy of such means.

E. In such cases, massage, also, crushing, and the sub-cutaneous punctures, might be made trial of. The fact is known, that sero-sanguineous liquids, when they once become encysted or enveloped in a sac, whether serous or fibrinous, are reabsorbed with extreme difficulty; whereas, when infiltrated into the cellular tissue, they in general readily and rapidly disappear. Every thing, therefore, goes to show, that if by massage, or any kind of compression whatever, we could succeed in rupturing the hematic cysts, we should have reason to hope for a cure. By inserting a needle under the integuments, so that it might pass obliquely and break up the sero-sanguineous pouch, we should also be enabled to force the morbid fluid to effuse itself into the neighboring cellular tissue. If we should combine with this process, compression or temporary blistering, it might also be frequently attended with success. With these exceptions, we must come to the seton and complete incision into the cyst or the multiplied incisions.

F. *Seton*.—The treatment of hematic cysts by the seton, is not a new mode of cure. Surgeons of all ages have occasionally boasted of its efficacy. We may conceive, in fact, that this means, by the inflammation and suppuration which result from it, might bring about the fusion (*fonte*), evacuation, and cleansing of the sac. The operation, then, may be compared in every respect to the one for hydrocele, by the same remedy. It is just to remark, however, that the clots, concretions, and various layers, which are then degenerated (*denaturées*) in the interior of the cyst, often prevent the seton from succeeding, and that the inflammation thus produced sometimes takes on a serious character, and but rarely progresses in a manner favorable to the cure.

G. *Incision*.—When kept up by the presence of morbid fibrinous concretions, hematic cysts would seem to demand, above all things, that they should be extensively laid open in order to extract from them these foreign bodies. Under this state of things, we should

proceed in the same way as was done in the time of Celsus in the operation for hydrocele by incision; that is to say, that after having freely laid open the tumor by means of a sharp-edged bistoury, we should empty it and thoroughly evacuate it both of its liquids and all kinds of concretions that might have accumulated there. Having thus properly cleansed it out, it is to be filled with small balls of soft lint, and then covered with the perforated linen, a plumasseau, compress and containing bandage. When the process of suppuration has sufficiently saturated this first dressing, the different portions of it are to be daily renewed, and we proceed to the end of the treatment the same as for an abscess, dressed flatwise and largely opened. This method, which is without contradiction one of the best, has, nevertheless, the disadvantage of not being applicable without danger in every region of the body. In the first place, it would be hazardous to think of it for cysts which exceed the volume of the fist, in whatever locality they might be situated. If, though, of less size, the tumor should be bridled by certain tendons, ligaments, muscles, vessels or important nerves, there would be danger in dividing it through and through. It is, moreover, useless to do that in the immense majority of cases.

II. *Multiplied Incisions.*—It is besides sufficient for the treatment of this class of cysts, to cleanse out their interior thoroughly and to create many openings for the fluid which is constantly tending to become re-accumulated in them. For that purpose I have been for a long time in the habit of treating them by incisions of about an inch in length, and which should not be wider apart from each other than an inch or two, so that I make a variable number of them according to the dimensions of the tumor. The first being made by puncture, enables me to introduce into it my finger, which then serves as a guide and support for the others. Directed through these incisions moreover, the finger enables us to detach and extract whatever there may be of a concrete or foreign nature in the tumor. In order to prevent their primitive agglutination I frequently pass from one to the other a meche of ravelled (effilée) linen, in form of a seton, and which I do not permanently withdraw until after the complete establishment of the suppuration. To set out from this period the disease is to be treated like a vast abscess: emollient cataplasms, and then resolvents and compresses saturated with lotions of the same nature, are the only topical applications which can now be of use. The concretions which often adhere to the interior of the cyst in the form of concentric laminæ, are fused and gradually decomposed, and imperceptibly detached and eliminated by the inflammation, and finally escape with the product of the suppuration. After the discharge of all these foreign bodies, the pus, which assumes a better aspect, diminishes in quantity, and allows the engorgement of the tumor gradually to subside, while the walls of the cyst approximate, unite together and become consolidated. It is precisely because of these concrete matters formed from the blood, that hematic cysts do not generally heal until after having been transformed into abscesses and submitted to the treatment most suitable for this last disease. The seton properly so called, and the simple incision, are of less value than the multiplied incisions, because they do not like these

last permit the immediate escape of the foreign bodies and the flow of the pus in proportion as it is formed; from whence it results that at a later period it becomes necessary most usually to superadd multiplied incisions to the seton and simple incision.

I. *Extirpation*.—Sanguineous like all other cysts, seem sometimes to be incurable except by extirpation. But this operation, which is usually long and delicate, and sometimes difficult and dangerous, is no longer admissible at the present day, unless the tumor should have undergone some degeneration of a bad character, or some lardaceous or fibro-cartilaginous transformation. If the diseased cyst could be removed in its totality, it would put it in our power to re-apply the flaps immediately over the bottom of the wound, and to treat the solution of continuity by first intention. In whatever manner done, it is easily understood that this treatment would not be applicable except to tumors that were not of large size and that were sub-cutaneous or inter-muscular. Multiplied incisions moreover, which almost always succeed and which are applicable to all cases, do not exact much more time than extirpation to accomplish a radical cure. Extirpation, as respects the operative process, the danger and the consequences of every description, is upon the whole infinitely more serious, without presenting more certainty of success than the multiplied incisions, and apart from some cases of exceptions, I cannot see that it can scarcely ever become indispensable to give it the preference over the latter.

§ II.—*Sanguineous Cysts, according to the region in which they are situated.*

Every effusion of blood having the power to produce an hematic cyst, there is reason to believe that no region of the body can be exempt from this kind of tumor. Whether we examine them in general or particular, it is nevertheless advisable to distinguish them always into two great classes—cellular hematic cysts, and the mucous and synovial hematic cysts.

A. *Cellular Hematic Cysts*.—The first, that is to say, those which are formed in the midst of the cellular tissue, or external to the mucous bursæ, cannot be studied separately as respects operative surgery. I will remark only in regard to them, that every effusion of blood of this kind should be treated, for a month at least, by topical resolvents, compression, massage, crushing, or temporary blisters, before coming to operations, properly so called. Two principal reasons induce me to give this counsel: the first is, that every hematic deposit retains a certain tendency to resolution up to the expiration of the first month, and that if inflammation should not supervene, crushing and blistering succeed quite frequently; the second reason is, that in opening the sac in such manner as to admit of the air penetrating into it from without, we thereby usually excite in it an inflammation of a sufficiently bad character, which readily takes on the form of erysipelas, properly so called, or angeioleucite or phlegmonous erysipelas. At a later period, when the hematic collection becomes completely encysted, the chances of cure by simple means diminish from day to day, while the concentration of the organic lamellæ, which become approximated to each other in order to form the en-

velope to the deposit, diminish in the same proportion the dangers of the operation. The tumor now differs scarcely in any respect from those which have been established in a previously existing cyst, or in a synovial sac. As for the rest, the operations which may be made trial of in such cases, are either the pure and simple incision on a depending part of the sac, the laying of it open completely, or the multiplied incisions. Caustics, the seton, irritating injections, or extirpation, would in general be insufficient or useless in such cases. The operation, moreover, will have to be submitted to the same principles, whatever may be the region of the body to which its application may be useful; and it is in anatomy alone that the surgeon must find the rules for his conduct in hematic tumors of this species particularly.

B. *Synovial Hematic Cysts*.—When the hematic cyst has established itself in a previously existing mucous bursa, there is scarcely reason to hope for its cure by resolution after the first three or four weeks of the disease have passed by. Should there be ever so few clots or concretions in the cyst, it is almost impossible for topical applications, injections and temporary blisters to succeed, and crushing would both be of little effect and extremely difficult. In those cases, therefore, the operation, properly so called, may be proposed without waiting as long as for hematic cysts of the cellular tissue. We may easily conceive that all the mucous bursæ might possibly become the seat of similar cysts; there are, however, some in which they are developed much more frequently than in others, and so to speak, exclusively.

I. *In the head*, for example, hematic cysts have been but rarely observed in the synovial bursæ. It is not the same we shall see with the cellular cysts, (see *Hydrocephalus*.) Upon the temporo-maxillary articulation, at the angle of the jaw or on the symphysis of the chin, the incision through and through would present no difficulty, might be performed as for the opening of an abscess, and might be preferable to the simple incision, unless we should wish to recur to puncture and irritating injections.

II. The mucous bursa of the *thyroid* cartilage, and that of the diaphragm muscle, should they become the seat of a sanguineous effusion, are to be treated in the same manner, unless the tumor shall have acquired a great volume, or the walls of the cyst have undergone a great degree of attenuation. In this last, the irritating injection, if there are no foreign bodies to extract, and the multiplied incisions, under opposite circumstances, should be substituted to the other method.

III. What I have said of the thyroid angle, is applicable in every respect to the mucous bursa of the *seventh cervical vertebra*, and that of the anterior surface of the sternum, and of the summit of the angular projections, (*du sommet des gibbosités*;) but when the cyst is established upon the sides of the spinal column, in the lumbar region, or on the external surface of the muscles, especially the *latissimus dorsi*, it is rare that the total incision of the cyst should have the preference. Supposing the tumor should consist of matters purely liquid, a puncture to empty it, and an iodine injection to inflame it, would almost always effect a cure. If grumulous products, concretions and clots of degenerated blood existed in the sac, to such extent

as to render the success of the injection doubtful, we must then have recourse to multiplied incisions and meches of ravelled linen, (see above.) Six incisions of an inch and a half each thus effected the cure of an hematic tumor which had formed between the spinal vertebræ and the upper part of the arm of a man who was admitted into my division of La Pitié in 1832. A young man who had a similar cyst at the lower part of the lumbar region, was cured of it at the expiration of a month by four incisions of the same kind. A woman, in other respects in indifferent health, and whose life has since been threatened by a diffused erysipelas, had for the space nearly of a year, between the spine and the lower angle of the scapula, a tumor, resulting from a blow, and having half the volume of an adult head. Having laid open this tumor freely on four opposite points, I afterwards passed two setons through it, which were removed at the end of a week, and nothing further has been required to complete the agglutination of the walls of the sac.

IV. The mucous bursa which covers the lower angle of the *scapula*, is quite frequently the seat of hematic extravasations. A young man formerly employed in carrying a hod, presented at the hospital of La Charité, in 1836, an instance of a tumor of this description which was equal in size to two fists. I opened it in three places, and the cure ultimately took place; but the natural mobility of the osseous angle and of the latissimus dorsi and trapezius muscles, presents in this part such obstacles to the obliteration of the cyst, that at the present time I would endeavor before all other things to produce an inflammation in its interior by means of the iodine injection, should it not appear to contain too great a proportion of concrete matters. The simple incision, to which a preference was given in the patient mentioned by Maréchal, (*Nouv. Bibl. Méd.*, t. I., p. 455, 1818,) and who had a bilobate cyst upon the shoulder, brought on a suppuration which ended in death.

V. Upon the dorsal portion of the *acromion*, hematic cysts might be treated as in the general track of the spine. Those on the contrary which form between the deltoid and the scapulo-humeral capsule, would require that we should confine ourselves to the simple incision, as I have done in two instances, or to the iodine injection. This last remark is alike applicable to the sub-tendinous cysts of the olecranon, the sub-muscular cysts of the coronoid process, and sub-bicipital cysts of the radius. Upon the inner condyle of the humerus they would require the same treatment as for that upon the spinous process of the seventh vertebra. The same would be the case for those on the styloid processes of the radius and ulna, and for those on the dorsum of the metacarpo-phalangeal articulations. But the sub-cutaneous mucous bursa of the olecranon, and the synovial cavities of the wrist, require in this respect some special precautions.

VI. *Hematic Cysts of the Olecranon*.—I have noticed in the sub-cutaneous mucous bursa at the elbow all the varieties of hematic effusions. If the effusion is in a liquid state and we are called shortly after the accident, topical applications, compression and the blister should be first made trial of. At a later period, if the tumor is voluminous and almost exclusively filled with fluid matter, puncture and the irritating injection are almost always sufficient. Should the mu-

cous cavity contain at the same time those granulations which resemble rice, barley or millet seeds, and which some persons have mistaken for hydatids or cartilages, puncture and injections no longer have the same efficacy. Multiplied incisions should then have the preference. Though exposing to phlegmonous erysipelas, they are less dangerous than extirpation and succeed full as well, without requiring so long a time for the definitive cure. If, in the place of this appearance of boiled rice or barley, the matters contained in the cyst should simply present the aspect of grumous substances, concretions or ordinary clots of fibrine, the same treatment should still be preferred.

VII. *Hematic Cysts of the Wrist*.—I do not mean under this title either the spiroidal (spiroïdes) tumors which sometimes form in the sheath of the tendons of the thumb on the outer side of the radius, or those bumps (bosselures) of the same nature which are sufficiently often noticed upon the palmar surface of the fingers upon the track of the flexor tendons of those organs; but of the kind of cyst which has for its special seat the synovial cavity in the palm of the hand and on the palmar surface of the wrist. This tumor, of which some examples are found in the ancient collections of observations, but which nevertheless has only attracted attention since the time of Pelletan and Dupuytren, has this remarkable feature, that it is divided as it were into two parts by the anterior annular ligament of the carpus, in such manner that one of these portions projects from the palm of the hand, while the other presents itself above it. Conveying moreover the sensation of a crepitation or friction of granulous bodies gliding upon each other, and a kind of fluctuation when alternately compressed at its two extremities, it is in general easily diagnosed. Having sometimes found them filled with clots of blood, which may still be recognized though comminuted (*morcelés*) I have ultimately come to this conclusion, that the grains of which they are usually composed and which are almost always found in them to the amount of some hundreds, far from belonging to the class of hydatids, as Dupuytren believed, or to that of loose (*libres*) cartilages, as others have supposed, were in fact nothing else than fragments of degenerated (*denaturée*) fibrine or plastic lymph. Whatever may be their nature, these tumors, denominated *bisaculated* (*en bissac*) tumors of the wrist, should be first attacked by every other kind of remedy than that of the cutting instrument, especially by repeated temporary blistering, seeing that no actual operation can be employed for them without danger. The irritating injection, which would be the mildest remedy for them, if liquid matter predominated in the cyst, is without efficacy in other cases. A large seton passed from above downwards through the whole length of the sac might doubtless succeed; but inflammation so readily extends to the palm of the hand, the tendinous sheaths of the fingers and the synovial networks and cellular tissue of the fore-arm, that it becomes the source of real dangers, and sometimes proceeds to the extent of compromising the life of the patient, or at least the preservation of the limb.

What I say of the seton is applicable also to the simple incision on one of the prominences of the tumor, or to multiplied incisions,

or the laying open of the whole tumor, including in this division the anterior ligament of the carpus. I know that F. Aquapendente, Portal (*Hist. Anat.*, t. II., p. 227), Schmucker, (*Bibl. Chir. du Nord*, p. 21), Gooch (*Encyclop. Méth. Chir.*, t. I., p. 545), and Dupuytren (*Gaz. Méd.*, 1830, p. 311, no. 34,) have met with success from the incision, and that Warner (*Obs. Chir.*, obs. 15 and 16, p. 88,) was enabled to divide the anterior ligament of the carpus with impunity, and thus effected cures; but I have seen such frightful results from this method at the Hotel-Dieu and Hospital of St. Louis, that I would scarcely dare recommend it. It is to be added also, that under the most favorable circumstances possible, the walls of the cyst operated upon in this manner, cannot agglutinate without causing such adhesions and confusion of the tendons, which course through the wrist, that a deformity of the hand or of the fingers would be the almost unavoidable result. In this region then, hematic cysts are a species of *noli me tangere*; and we should be on our guard against meddling with them so long as the patients are not greatly incommoded by them, and not until after having made trial of all other remedies, and forewarned the family of the possible consequences of such an operation.

a. As for the rest, when once decided upon, the operation which I should then advise would neither be the seton, nor the simple incision, nor the complete laying open (*la fente totale*) of the sac; I should much prefer three or four *free* (large) *incisions* upon the principal projections of the cyst, which I would then treat as a large (*grand*) abscess, by emollient topical applications, local sanguineous emissions, and all the different kinds of antiphlogistic remedies. Having seen a young person operated upon by means of the simple incision, by M. Richerand, on the point of dying from the inflammation which seized upon the whole hand and fore-arm, and knowing the consequences of this kind of treatment, as pointed out by Dupuytren, I should not venture upon it but with the greatest repugnance. The two patients in whom I used multiplied incisions having got well, encourage me, on the contrary, to commend this last mode of operating, without, however, presenting it as exempt from all danger. I should add, that in a young man operated upon by me at La Pitié, in 1832, the hematic cyst though very ancient, contained concretions of fibrine and clots of blood still recognizable, but without any of those grains of which I have spoken of above. The four incisions which I made upon it above were followed by an inflammation sufficiently intense to give me at first some degree of uneasiness; but the accidents ultimately subsided, and the cure was accomplished at the expiration of the second month.

b. A *puncture* and a *small incision* aided by compression, have also succeeded so well with M. Champion, that it is well to have recourse to it again. M. Duval, manufacturer of cotton fabrics, consulted me (says this practitioner in a letter to me,) in the year 1810, for a ganglion of a sufficiently large size, which raised up the skin in the palmar surface of the hand, and which was prolonged upon the lower third of the fore-arm, by passing under the annular ligament of the tarsus, which divided it into two bellies. Having used the bandage of Theden for the space of six weeks, without

success, I plunged a bistoury into the lower part of the tumor upon the fore-arm, which brought out more than six ounces of liquid, to which there succeeded soon after, about two teaspoonfuls at least, of small foreign bodies of the size of the eggs of the carp, and of a reddish color, and a slight degree of hardness. The compressive dressing to the hand had been reapplied before the operation, and I continued its application to the cyst, and the whole limb as high as the axilla, by means of a bandage kept moist with oxycrat and salt, cold. The incision, which at first was only four lines in length, had to be enlarged to effect a passage for the small granulated bodies. No accident took place, and scarcely any inflammation supervened. The dressing, or the roller bandage, was continued for a month, restricting it soon to the surfaces which corresponded with the disease, and the cure was complete. I operated, says M. Champion, upon a second and similar case in 1822; only that the tumor was of less size. The incision gave egress also to concretions, but in smaller quantity, and the success was the same.

VIII. The *Lower Limb*.—If the mucous bursa of the antero-superior spinous process of the ilium should be transformed into an hematic cyst, it would become necessary to attack it like that of the olecranon. It would be the same with that on the outer border of the great trochanter, and on the outer surface of the thigh. I have met with one example in front of the spine of the tibia, and which disappeared under the influence of two temporary blisters. The same took place in the case of an hematic cyst at the head of the fibula. The sub-cutaneous hematic cysts upon the posterior surface of the heel, and upon the dorsal and inner side of the scaphoid bone, the projection of club feet, and the dorsal and inner side of the first and other bones of the metacarpus, do not exact also other precautions than those of the corresponding regions of the hand. Upon the stump of persons amputated, these tumors should not be treated but with a certain degree of reserve, inasmuch as their suppuration, from their being situated on the apex of the bone, would obviously expose to necrosis. Between the great trochanter and the coxo-femoral articulation, between the gluteus minimus muscle and the same articulation, between the obturator internus muscle and the lesser sciatic notch, under the tendon of the iliacus internus muscle, upon the apex of the little trochanter, between the triceps and the rectus femoris, under the ligamentum patellæ and between the tendons of the pes anserinus, between the os calcis and the tendo achillis, where I have met with three examples, also on the plantar surface of the foot,—hematic cysts if somewhat ancient, scarcely ever yield to the application of topical resolvents, nor even to large temporary blisters. As on the other hand there is some danger of producing suppuration, they should be treated by puncture and irritating injections, provided they contain a sufficiently strong proportion of liquid matters. In the contrary case, I know not in reality which should have the preference, whether the seton, the simple or multiplied incisions, or the complete division.

IX. I have often observed hematic or sero-sanguineous cysts upon the dorsal and inner regions of the metatarso-phalangeal articulation of the great toe. In this place temporary blistering and topical ap-

plications of all kinds should be made trial of before proceeding farther. Supposing such means should produce no effect, we should not even then come to the operation, unless the tumor was in reality a source of serious annoyance to the patient. These mucous bursæ are so near the articulation, with which moreover they sometimes communicate, that we should never divide into them or lay them open, nor, in a word, carry the cutting instrument upon them unless compelled to do so. I have seen two patients upon the point of perishing in consequence of such attempts, and through means of a suppuration, which after having invaded the articulation ultimately left therein caries which rendered amputation necessary. Platner, (*Coll. Acad., partie étrang.*, t. VIII., p. 43, du Discours Préliminaire; also Paul, *Suppl. à la Chir. d'Heister*, p. 50.) speaks of a ganglion of the synovial cyst of the tendo achillis, which having acquired an immense size, was followed by serious accidents, though nothing had been done to it. I saw, says M. Champion, a synovial ganglion of the same kind eight years since, in a woman aged 36; it was of the size of the fist and its form was elongated. I recommended puncture and compression, and rest for the space of a month and more. The patient more alarmed at the period of time than the operation, consulted an officer of health, who promised he would make a more speedy cure. An incision was made; and soon after a fungus formed on the inside surface of the cyst, and acquired a very considerable size, ending in the death of the patient.

X. The mucous bursa on the dorsum of the foot, which I have seen transformed into an hematic cyst in three instances, would require the same precautions, though there might perhaps be a little less danger of the inflammation prolonging itself to as great an extent as in the preceding case.

XI. The malleolar hematic cysts I have met with, have all been treated by the multiplied incisions; but it would be prudent to attempt their cure by irritating injections if they contained a large proportion of liquid matters. The neighborhood of the fibro-synovial sheath of the peronei tendons on one side, and of the tibialis posticus on the other, together with the character of the tibio-tarsal articulation, should always make us avoid as much as possible the establishment of a purulent inflammation in that quarter.

XII. It is upon the knee that hematic cysts are the most frequently met with. Those which develop themselves upon the outer or inner condyle of the femur, rarely acquire a large size, and may be treated by crushing, sub-cutaneous puncture, or irritating injections, when they have resisted both topical resolvers and temporary blistering. There will be opportunity moreover after these means, to attack them by a complete division or by multiplied incisions rather than by the seton.

XIII. Those *in front of the patella* and which are so often encountered in practice, and of which I have seen so great a number of varieties, require especially that I should allude a moment to them. In this part I have met with them of the form of a plate of little thickness, four or five inches long and from two to four fingers' width in breadth; at other times presenting a bi-sacculated appearance, or an irregularly embossed (*bosselée*) mass, or hemis-

spherical, or taking on the character of a transverse bourrelet [like a collar, T.] I have seen them of the size of the fist, though ordinarily they do not exceed that of a pullet's or turkey's egg. Sometimes filled exclusively with liquids, either viscous, or purely serous, or lactescent, and of a reddish brown or simply a roseate tint, they very often also contain clots of a fibrinous or reddish matter, still possessing most of the characters of clots of blood; sometimes simple greyish or yellowish clots that are friable, or as it were, cartilaginous and exceedingly variable in number; at other times a species of columns or movable bridges that are hard and slippery and of a cartilaginous aspect, and adherent by one of their extremities or even by both, so that in pressing them upon their exterior they convey a sort of crepitation which is sufficiently distinct and altogether of a peculiar character. The extirpation of these cysts, which MM. Pezerat (*Journ. Compl. des Sc. Méd.*, and *Bibl. Méd.*, 1827, p. 414) and Hervez (*Journ. Hebd.*, t. III., p. 329,) still seem to prefer in adducing facts in support of it, would not become indispensable unless their walls should have acquired an extreme degree of thickness, and a fibro-cartilaginous density. In such cases we should proceed in the manner pointed out for concrete hematic tumors. When the cyst is not of a very ancient date and [its contents] almost exclusively liquid, it is advisable to commence with topical resolvers, compresses saturated with ammoniacal vinegar or any other solution of sal ammoniac. The temporary blister would come in as a second remedy. I have seen a certain number of hematic cysts of the knee, which had existed over three weeks, dispersed by employing this description of remedy. [Our author (see Vol. I.) means by temporary blistering (*vésicatoire volant*) the successive application of small blisters composed as usual of Spanish flies, combinations of ammonia, &c., left on for a short time and changed in their locality. Vesication is not intended, but only a phlogosis or commencing inflammation, redness, &c., so as strongly to direct the sanguineous and other currents to the part. So far however from this temporary or transient mode of applying blisters, and which the author much insists on as an extremely valuable remedy, being a reliable one here, we ourselves have, on the contrary, found even in these largest sub-cutaneous mucous (properly *serous*, see our notes *infra*) bursæ, of old date, i. e., a year or more, and covering the whole patella of an adult, being like a large inverted cup, effectually cured for a length of time by means of a continuous copious drain of suppuration kept up on the dermoid surface of the tumor by thorough, repeated and full blistering, i. e. by the ordinary mode of applying this remedy. However, as I have repeated, (Vol. I.) *bursæ* of the largest description, provided their contents are liquid, and their walls and the neighboring tissues are not intensely inflamed, are, whatever may be their date, best and most effectually and radically cured by *percussion*, i. e. *écrasement* or crushing, &c. T.] At a later period we would have but little to expect from topical applications and the blister. We must then endeavor to ascertain if it is liquid matter, or concrete, that fills the synovial bursa. In the first case iodine injections would have a decided preference over every other preparation. I have made use of them on three occasions under

such circumstances, and the result has been as simple as in a case of hydrocele. The trochar being plunged in at the summit of the tumor from below upwards, while the leg is in extension, enters into the cyst as it does into the tunica vaginalis, allows us to extract all the liquid, and afterwards to inject into the cyst the medicated compound with the greatest degree of ease. Similar successes also were obtained formerly by various practitioners, and in our own time by M. Asselin, who gives two fine examples of them; also by M. Paul Guersent, as well as by M. Laugier.

The efficacy of irritating injections for cysts in front of the knee, therefore, is at the present day a point definitively adjudged. When the cyst, on the contrary, contains a sufficiently large proportion of solid clots, it is probable, though not yet demonstrated, that the injection might not be successful. The most suitable operation then, is not that of the seton; the pure and simple incision, with the introduction of a tent into the cyst, which I have done four or five times, is far from being always successful. The walls of the tumor only partially agglutinate, and the effusion generally is ultimately reproduced. The tumor returned in three patients that I operated upon, and the other cases were cured only by means of a violent inflammation, which speedily involved the whole anterior portion of the knee. It is necessary, moreover, in all cases, that this incision should be near an inch long, if we wish to have no difficulty in the discharge and extraction of the foreign grunous bodies contained in the cyst. The crucial incision also, which I have sometimes made use of, and which many practitioners have sanctioned, is an operation too serious in its consequences, and leaves a wound of too great length and too difficult of cicatrization to merit general adoption. The same may be said of excision, which was still employed by Percy or by Laurent, (*Eloge de Percy*, p. 25.) Multiplied incisions, consequently, are those to which I give the preference in these cases. These incisions being made of about an inch in length, and placed one above, another below, and one on each side, and as near as possible to the circumference of the sac, and whose agglutination is prevented by means of a meche of ravelled linen during the first four or five days, enable us to empty the sac completely, and thus create an inflammation in it, which almost unavoidably results in the consolidation of its walls. Certain it is, that the patients treated by me in this manner, have all been cured in the space of from three to six weeks. I ought, however, to add, that in a man operated upon in this manner in 1837, at the hospital of La Charité, for an hematic cyst at the elbow, the disease in consequence of another fall on this part, was reproduced in 1838. We must, moreover, not forget that sudden movements, as well as the want of proper care in the dressings, would incur at the knee more than in any other part, the risk of angioleucitis, erysipelas, and diffused phlegmons of a formidable character. I have only in three instances seen the sub-ischiatic mucous bursa, transformed into a sanguineous cyst. In this region the disease may present some difficulties in the diagnosis; but it should be submitted to the same processes of operation as in front of the knee, and the suppuration would be far less dangerous than in the vicinity of this latter articulation.

## ARTICLE III.—SEROUS CYSTS.

Under the title of serous cysts, we should, strictly speaking, comprehend all tumors consisting of a pouch, filled with aqueous liquid. We should thus designate under this name the greater part of hematic, hydatid, and synovial cysts, as well as all serous cysts properly so called. Under the title of serous cysts, however, I shall speak only of those tumors which are independent of the natural mucous or synovial cavities, and which are constituted of an unnatural accumulation of diaphanous and exceedingly fluid liquid. All that I shall say of them, moreover, is exactly applicable to synovial cysts of the mucous bursæ, and to those tumors known under the name of *hygroma*. This description of cysts does not belong only to those exhalations, which sometimes take place in the midst of the cellular tissue, and without any appreciable degeneration. A lymphatic ganglion, or any glandular organ whatever, or the presence of any foreign substances, may become the source from whence it originates. An enormous cyst occupied the entire supra-hyoid region from one parotid cavity to the other; M. Malcolmson (*Gaz. Méd.* 1838, p. 743) excised an ellipse from it below the jaw, and the liquid escaped together with a foreign body. But a kind of gland was noticed at the bottom of the sac; this gland being secured with a hook and excised, and, in fact, extirpated almost in its totality, had the appearance of belonging to the sub-maxillary gland. Was it not, perhaps, a degenerate lymphatic ganglion? at least the serous cyst was certainly dependent upon it. Marchettis (Bonet, *Corps de Médec.*, t. III., p. 239, obs. 38) speaks of a tumor of the size of a pullet's egg, situated in the neighborhood of the trachea, and composed of two cysts full of serosity, and imbedded one within the other. The author adds that there was at the bottom of the sac an excrescence which it became necessary to excise, which authorizes us in suggesting that a lymphatic tumor had been the point of departure of the disease. Muralt (*Ephémérides des Cur. de la Nat.*, dec. 2, an. III.) also speaks of serous cysts which contained either bones or other foreign bodies, as well as a pound weight of serosity. In 1838, a man came to the hospital of La Charité, who had a tumor in the scrotum of the size of two fists, with all the characters of hydrocele, from which about two glasses of a rose-colored serosity had been already extracted by puncture a year before, and which was soon afterwards reproduced. Suspecting that this cyst depended upon a degenerate hematocele, I operated upon it with the multiplied incisions. Various accidents supervened, and the patient died at the expiration of fifteen days. But this cyst, which contained more than ten ounces of a liquid almost entirely serous, was the result of an encephaloid degenerescence of the testicle, which latter, however, had only augmented to about double its natural volume. I have, moreover, seen cysts that were purely serous, form in the groin, under the jaw, and in the sub-hyoid region, in consequence of previous diseases in the lymphatic ganglions, or in the thyroid gland.

The preceding remarks were necessary to show that serous cysts are far from always constituting a simple disease, or from being all

of them susceptible of dispersion with the same certainty by the action of the same remedy. I will add, that after contusions or bruises which occasion infiltrations or extravasations under the skin, we see quite often the coagulable and coloring matter of the blood disappear, and give place to a serosity or viscous or unctuous fluid, which is almost in every respect analogous to the synovial fluid. Serous cysts, in whatever way produced, may acquire an enormous volume. According to Percy, (*Dict. des. Sc. Méd.*, t. XXVII., p. 50) Levret met with one which extended from the dorsal region to the ham. Powel, (*London Med. Jour.*, t. II., p. 144, 1785,) gives another example of one which was cured by incision, and which descended from the shoulder to the spine of the ilium. Their ordinary size, nevertheless, rarely exceeds that of a pullet's egg, or the head of an infant or of an adult, [being at the same time] more or less irregularly deformed. The shape and size of a round loaf of bread, as in the case mentioned by Saucerotte, (*Mél. de Chir.*, t. II., p. 391,) is however by no means extraordinary. These cysts, moreover, may be developed on almost all the regions of the body. All practitioners know that the free border of the lips and eyelids are frequently the seat of tumors of this kind, which rarely exceed the dimensions of a small bean, and for the speedy cure of which, all that is requisite is to lay them open and cauterize them with nitrate of silver. Jourdain, (*Malad. de la Bouche*, t. II., p. 195,) a long time since, noticed the presence of serous cysts in the substance of the lips. M. Pl. Portal, (*Clin. Chir.*, p. 289,) gives an example of one upon the lower lip. I have met with them of the diameter of an inch or the half of an egg, once on the anterior region, and another time on the side of the right parietal bone. M. Champion, (communicated by the author, 1838,) operated for one of the size of a small pullet's egg, and situated under the left temporal muscle. In Heister also (*Thèses de Haller*, t. V., p. 241, French translation,) we meet with an example of a serous cyst as large as an egg, which had developed itself under the ear. In another patient, whose case M. Champion has transmitted to me, the tumor, which was bilobate and situated between the muscles, occupied the left portion of the supra-hyoid region, and projected at the same time within the mouth as well as below the jaw, where it was equal in volume to a turkey's egg. I have also seen, in the same situation, a similar cyst of the size of the fist, in an infant aged twenty months. In treating of the operations which are performed on different regions of the neck, I shall have to return to the serous cysts, which are sometimes produced by affections of the thyroid or of the salivary glands. The surface of the thorax is sufficiently often the seat of similar cysts. Rudolphi (*Jour. Analytique*, 1828, No. 7, p. 103,) mentions one under the pectoralis major, and which resembled a schirrhus. I have also seen one which was of the size of two fists, in a boy aged fifteen years, and which being situated in front of the axilla, presented the form and other appearances of a firm and well-developed mamma. Heister speaks of a cyst of this description which was situated on the side of the spinal vertebræ; and I have frequently met with cysts on the different regions of the back, which, though of hematic origin, were nevertheless completely filled with serous liquid. Though M. Basletta (*Bullet.*

*de Férussac*, t. X., p. 95,) was successful in curing his patient of a cyst of the size of an egg, filled with palish (pallacée) matter, and situated deep within the abdominal walls, and communicating with the peritoneum, it was not so with M. M'Farlane, (*Encyclop. des Sc. Méd.*, 1836, p. 55,) whose patient died after the puncture of the cyst, which was between the peritoneum and muscles. M. Tavernier speaks of one which was situated between the abdominal muscles, and which, having made an opening into the belly, also caused death. In the collection of M. Ouvrard, we also find an instance of a serous cyst of considerable size situated upon the back. A serous cyst of the size of an orange was successfully removed by M. Pl. Portal from the back of a man aged fifty years, (*Clin. Chir.*, p. 231.) Serous cysts have been noticed upon the breech by M. Récamier, (*Gaz. Méd.*, t. I., p. 319, No. 35,) and a great number of other practitioners. I have myself often seen them in this region; but it is at the fold of the groin where they are most frequently found, and where I have met with them of the size of a child's head.

M. Jaudard (*Thèse*, Strasbourg, 1816, p. 14, obs. 4) states that he saw one at Lyons in the service of M. Bouchet, which was situated about the middle of the inner part of the thigh. That mentioned by Paroisse (*Journ. Gén. de Méd.*, and *Dict. des Sc. Méd.*, t. XXII., p. 133,) occupied at the same time the thigh and the leg. I have often had occasion to meet with them on the different regions of the arm and fore-arm, on the body of the thigh and leg, and on the foot and hand. All the *operations* I have described for hematic cysts, are applicable to those that are serous. Leaving aside what relates to the employment of topical applications, compression, blisters, and even caustics, I would remark that crushing and puncture with the needle would not succeed, except in certain cases, and should not be had recourse to unless it should be impracticable to make use of irritating injections. This last means, in fact, especially if tincture of iodine be employed, is so perfectly simple and of such unfailing efficacy, that it should be preferred in every case where no particular operation would forbid its employment. Should the cyst not be very large, we should make use of a very delicate trochar and a syphon-syringe corresponding. In other cases we should proceed in the same manner as in the operation for hydrocele, and should succeed equally well. Supposing, however, whatever the reason may be, that we do not wish to make trial of this remedy, an opportunity would then present for puncture or the simple incision of the cyst: this sometimes suffices to bring on inflammation, suppuration and a definitive cure. A woman of 45. had in the left groin a tumor with thick walls, slightly *bosselated* (*bosselée*\*) on its surface, of the size of the head, but without ever having caused her any pain. This woman, who had been addressed to me at La Charité, had her tumor punctured by M. Vidal, who took from it two glasses of a limpid serosity. Finally, a purulent inflammation established itself in the

\* We shall venture on the coining of this word, as *bosse* and *bossel* (from whence *embossing* in English—i. e. sort of *basso relieve* or fret-work in the ornamental arts), are not translatable with precision, certainly not with elegance, by bumps, lumps, bunches, bumpy, &c., although they may rudely convey the idea of the inequalities, or elevations and depressions meant. T.

sac, and the pus opened for itself an outlet through the puncture which had caused it. The tumor was reduced little by little, to the volume of a pullet's egg. Seeing that the process of resolution was suspended, I considered it to be proper, before having recourse to a complete division of the sac, to make trial of a large temporary blister. Eight days after, the walls of the sac were found completely agglutinated, and the patient soon after demanded her dismissal from the hospital, being in a state of perfect cure. If however puncture or the simple incision should seem insufficient, we should come to the complete division of the tumor, should it not exceed a small egg in its size, or in the contrary case, insert through it one or several setons, or better still, divide it on several points of its free portion by means of large incisions. As to extirpation, it is neither more efficacious nor more certain in its effects than the preceding method; and as it is obviously the most dangerous and most difficult, and the longest of all, it would be advisable in general to reject it. Up to the present time I have not used the iodine injection for curing serous cysts, except in the boy who had one on the outer side of his breast, and in the infant who had so vast a one in the supra-hyoid region; but these two examples have satisfied me that a remedy like this will succeed in at least fifteen cases out of twenty, and that it should be made trial of before all others. Serous cysts developing themselves external to the natural organs and cavities, cannot be examined in a topographical point of view. The operative process which relates to them should consequently be submitted to simple general rules, whether it be crushing, puncture, injection, the seton, incision, or multiplied divisions, or finally excision of all its most attenuated portions, or its extirpation, when it is of too large a size to allow us to hope for perfect agglutination of its walls. Among serous cysts there are some that are multilocular [i. e. having several compartments, T.] or truly hydatid. In such cases we should have to qualify what I have said of irritating injections and the different kinds of incisions. It would be next to impossible here to look for a radical cure by means of the seton, the simple incision, or even the multiplied incisions, unless the operation, perchance, should include all the vesicles of the cyst. To operate then in such a case with any chance of success, it would be necessary to lay open the tumor throughout all the compartments (locules) of which it is made up, or to extirpate it entire. An hydatid cyst which existed in the iliac region was successfully extirpated by M. McFarlane (*Encyclop. des Sc. Méd.*, 1836, p. 54), and M. Colson (*Rev. Méd.*, 1827, t. IV., p. 33) found one of this description between the bladder and the rectum. Whether the tumor in this respect, in reality contain hydatids, or is composed purely of serous receptacles (vacuoles), the indication, notwithstanding, will be the same. It would only be a loss of time to attempt the other operative methods described farther back, and which, besides their little efficacy, would expose to real dangers.

#### ARTICLE IV.—SYNOVIAL CYSTS (NODUS-GANGLIONS).

Tumors known under the title of synovial cysts, were formerly designated by the name of ganglions or *nodus*, and it is these, which

people in general call *thickened, knotted or twisted sinews*, [nerfs foulés, noués or tordus—sometimes “weeping sinews.” T.] Developing themselves in the neighborhood of the joints, or upon the track of the tendons, these tumors rarely exceed the size of a nut or egg. All of them appear to consist of a sort of cul-de-sac or hernia, or appendix to the natural synovial cavities, whose neck (collet) had been obliterated from some cause unknown. They may be divided into two classes: 1. Articular synovial cysts; and 2. Tendinous synovial cysts. Nothing, however, is so variable as the development and progress of such tumors. Moinichen mentions having seen them disappear on the approach of parturition, and afterwards re-assume their primitive volume. M. Champion mentions having seen one which shrunk for several years successively, every two years, about spring-time; but it appears in this case, that the shrinking of the cyst was owing to the accumulation of the liquid producing a crevice. We may conceive that the disease then acts similarly in fact to a hydrocele, which has been accidentally ruptured, and is soon after reproduced. As synovial cysts do not ordinarily cause any pain, many patients will carry them all their lives, without applying any remedy or paying any attention to them. I have seen a woman fifty years of age, who had three of them about the abductor and extensor tendons of the thumb for more than twenty-five years. I have seen others at the dorsal region of the foot, about the knee, and on the track of the different tendons of the hand, which had existed to full as great a length of time, without the persons who were afflicted with them, ever having thought of applying any remedy to them. I should, in fact, add that many of these cysts ultimately, in the course of time, disappear spontaneously. They are not to be attacked by surgical means therefore, unless by their volume or relations, they produce either deformity, inconvenience or pain, or functional disturbance to such extent as to induce the patient to incur the *risk* of the operation.

### § I.—*Various Means.*

Nothing also, is more variable than the treatment for this description of tumors. M. Ch. H. (*Encyclop. Méthod.*, t. XIII., p. 617, col. 2, 1832,) had a ganglion of the size of a small nut, on the flexor tendons of the left ring and middle fingers. Having, in vain, consulted most of the distinguished physicians of Paris, the patient, who put himself upon the use of the muriate of soda, of which he took from two to three ounces a day, in this manner effected a radical cure. Gilibert (Rousset, *Thèse de Strasbourg*, 1812, p. 6,) says he has seen a case of this kind in which satchels of plaster, or leaves of lavender, succeeded. Frictions with aromatic, mercurial and camphorated mixtures, laurel oil, soap and water, saliva, resolvent plasters, hard and repeated rubbings and baths of sulphur-water, equally appear to have been followed by some successful results. Dupuytren, according to M. Bouboucki, (*Thèse*, Paris, 1828, p. 25,) dispersed a synovial ganglion in the ham, by means of the simple *douche*. But were it allowable to make trial of such remedies, it would be puerile to count on their efficacy, unless in some very rare exceptions.

§ II.—*The Temporary Blister,*

Or even one that is permanent, would deserve infinitely more confidence. Jæger, (*Dict. de Chir.*, t. I., p. 526,) who made use of them for cysts at the knee, asserts that he obtained positive advantages from them. I have elsewhere published (*Archiv. Gén. de Méd.*, 1826,) the case of a synovial cyst on the posterior region of the wrist, which disappeared under the action of two large blisters, though it was of very ancient date, and of the size of half an egg. I have often succeeded with the same remedy since, in similar cases. A lady, who had one of the size of a large nut, on the dorsum of the foot, opposite the calcaneo-cuboidal articulation, and who would not hear to an operation, was also cured by means of large temporary blisters and resolvent frictions, and compression. Though I might cite at least as many as ten analogous facts, I ought, however, to remark that most synovial cysts will not yield to this therapeutic.

§ III.—*Moxa.*

*Moxa*, which has already been made trial of for a cyst of the wrist by M. A. Severin, (*Méd. Efficace*, p. 550, § 1998,) and which M. Champion also says he has used with success in a patient who would not submit to any other means, would not probably be any more effectual, and has too many inconveniences in itself ever to become the favorite remedy for this disease.

§ IV.—*Caustics.*

Though the employment of caustics may have succeeded with F. de Hilden (*Centurie* 3, obs. 79, or p. 72; obs. 44 of the French translation,) in curing a synovial cyst of the carpus, and an arsenical application have been equally successful with Woolam, (*Annal Muyskezas*, t. III., p. 490, 1811,) such remedies, nevertheless, have in all epochs inspired the most vivid apprehensions. Dalechamps (*Chir. Fran aise*, p. 158, in-4°; p. 910, in-8°, 1570,) relates that a patient, with synovial cysts on the dorsum of the hand, who was treated for them by caustics, did not recover until after having experienced very severe inflammatory accidents. It is moreover evident that this kind of operation, would be exposed to all the consequences to be apprehended from a cutting instrument, without having its advantages. Their uncertainty and the deformed cicatrices which they would necessarily produce, will always be sufficient to proscribe their use with the generality of practitioners.

§ V.—*Compression.*

One of the remedies against synovial cysts which has been most extolled is compression; the ancient authors had already noticed it. La Vauguyon (*Traité d'Operat.*, p. 627,) recommends that it be made with a plate of lead, and that frictions be associated with it. This plate of lead, adjusted by a pelote and circular bandage, has been proposed anew by Marigues and Testat. (*Malad. Chir.*, 1786.) Theden, the great admirer of compression, says that by means of

this, with lotions of the arquebusade water, he cured a synovial ganglion in the space of six weeks. New facts also in favor of this remedy have been brought forward during the course of the present century, by M. Balme (*Dissert. an. X.*, p. 39,) and M. Godele, (*Rev. Méd.*, 1831, t. I., p. 19.) It is nevertheless true that compression alone rarely succeeds with synovial cysts, and that in order to obtain any cures from it, it would be necessary to apply it with such force and to continue it so long a time, that in reality it scarcely deserves to be made trial of except as an auxiliary to other operative methods.

### § VI.—Crushing, (écrasement.)

A more efficacious remedy, and one which surgeons have in their pride erroneously associated with the practice of vulgar people or charlatans who itinerate about the country, is that of crushing the cyst. This remedy, which at first sight appears so rude, had already been employed in the time of Philagrius, (*Peyrilhe, Hist. de la Chir.*, p. 702,) Chaumête, (*Enchiridion des Chirurg.*, ch. 3, p. 122, 1560,) and Forestus, (*Bonet, Corps de Méd.*, t. III., p. 60.) Muys (*Decad.* 2, obs. 8, p. 127; *Nouv. Obs. de Chir.*) armed with a leaden palette, cured in this manner a cyst at the wrist, and similar successes were obtained by Ledran (*Consult. de Chir.*, p. 257,) and by Godele (*Rev. Méd.*, 1831, t. I., p. 17.) I have, says M. Champion, often crushed ganglions in the palms of the hands, by means of the thumbs crossed, or by a single thumb; but there is a good number of them that will not yield to this kind of pressure. This practitioner, who agrees in this with Heller that crushing is very uncertain, almost always uses a mallet and a piece of paste-board cut in the form of a shovel. A single stroke properly applied ordinarily answers in such cases. This compression [rather *percussion*, T.] astonishes much more than it does harm. On the carpus and the tarsus it has never, says M. Champion, failed. A man who swooned away immediately after the stroke, confessed subsequently that it was from fear. This process, which the rebouteurs (rebouteurs) and peasants have employed from time immemorial to *untie the tendons*, requires that we should place the limb upon a solid support while making the stroke with the mallet, and that the cyst should afterwards be properly compressed during some fifteen days. I have often in my boyhood, seen peasants in the country strike the fist violently upon the wrist, and in this manner cure synovial cysts of the hand. I have seen others who did the same thing on the foot, and I should add, that unless there be a very considerable degree of muscular force exerted, we fail in most instances when we attempt to crush by the thumbs alone. This crushing [or sudden rupturing or bursting of the sac, T.] is in short an operation to be made trial of. It is, however, exposed to two inconveniences; sometimes there results from it an inflammation sufficiently acute, and I have seen three patients in whom it was attended with such accidents, that a vast suppuration was established in the limb, and their life for a long time kept in jeopardy.

When every thing goes on naturally, the tumor retains a great tendency to be reproduced; more than half of the synovial cysts which I have treated, or caused to be treated in this manner, have

returned at the end of some weeks, or some months. We should, however, render success more certain by associating with this remedy repeated temporary blistering, resolvent frictions, and compression for a long time continued.

[We refer the reader for the advocacy we have made of this invaluable resource of *sudden and powerful percussion*, to what we have said above of these bursal cavities or cysts, when they contain other than pure synovial fluid—to which the author here confines himself. Also to our remarks in Vol. I., and also *infra*, on the same mode of treatment. The cases in which we have used it, and we never employed any other remedy, were of the character of synovial cysts proper, in their normal state, so far as they were unchanged in structure and containing their normal sero-synovial fluid, only accumulated in abnormal quantity, therefore literally, as by the vulgar name, a weeping ganglion. In every case the blow made with great rapidity and force, by a heavy book held in both my hands, and at the height of two feet above the tumor as the limb lay firmly stretched on the table, I succeeded in perfectly and radically curing the disease, in an instant. The tumor entirely disappears under the blow which crushes it, so that the deformity, as if by magic, leaves thus the smooth natural plain surface of the skin. In one of the cases at the olecranon, where it appeared somewhat bosselated, the disease returned partially in a few weeks, but a second blow completed its extinction. In a very recent case, the tumor being of the size of a small nut and on the ulnar side of the dorsal surface of the radius, about two inches above the wrist, (caused in a stout young Irish porter from lifting heavy trunks,) and resting, in fact, partly on the interosseous space, I was enabled, by proper pronation, to bring the tumor on to the edge of the radius, and by this means procure a solid osseous point d'appui. I would recommend this course of pushing the tumor where it can be done, on to a bony plane, before the blow is struck. This I advert to, because I believe it practicable, in most instances, on the dorsal surface of the metacarpus, where the tumor lies on an interosseous space. In one such case I recommended it to a very bold practitioner, who nevertheless pursued his own course, opened the sac and caused a severe, if not dangerous inflammation. In striking the blow, it must be done with a good deal of force and with a heavy quarto book for example. In the cases of our author, whenever the disease returned, he was perhaps too sparing in this respect, towards his patients. This beautiful illustration of sub-cutaneous or sub-muscular, or even sub-aponeurotic surgery, (for I should consider a synovial tumor beneath an aponeurosis, provided the tumor could be made to rest on bone, equally curable by this mode,) excludes effectually every other treatment, and for myself, I never saw the slightest accident supervene from it. Nor have I found the least degree of compression necessary after the *ecrasement*. T.]

#### § VII. *Sub-cutaneous Puncture.*

Some surgeons, having confidence in the rupture of the sac, and experiencing some difficulties in effecting it, have proposed to introduce obliquely under the skin a cataract needle, and thus puncture

the little synovial pouch so as to allow of expelling its contents and forcing them to become infiltrated into the neighboring cellular tissue. M. Cumin, (*Journ. Univ. des. Sc. Méd.*; *Journ. Analytique*, t. I., p. 367, Nov. 1827; *Bull. de Férussac*, t. XIV., p. 225; *Arch. Gén. de Méd.*, t. XIV., p. 252,) who appears to have been one of the first to suggest this operation, recommends with reason, that we should make use of compression also after having emptied the sac. I have attacked in this manner a synovial cyst on the dorsum of the foot, another which was situated in front of the malleolus externus, and similar tumors on the back of the hand and wrist, without ever having obtained a single radical cure. The tumor was emptied and the sub-cutaneous layer of the neighborhood became slightly œdematous; but the cyst soon filled again and the disease reappeared as before, whatever M. Roberts (*Journ. des Progrès*, t. XII., p. 258; *Rev. Méd.*, 1829, t. I., p. 299) may say on this point. To obtain any favorable results from this means therefore, it would be necessary to associate with it not only compression, but also temporary blistering and resolvent frictions.

### § VII.—Seton.

*Puncture*, and the abstraction of the liquid by means of a syringe or gum-elastic bottle, as recommended by Monro (*Ancien Journ. de Méd.*, t. LXXIX., p. 138,) would be at the same time more difficult and also still *more uncertain*. The seton, which has been employed by quite a great number of practitioners, and which is mentioned by M. Ch. L. (*Encyclop. Méth.*, t. XIII., p. 618,) and also by M. Cooper, is considered by others (*Journ. de Méd.*, t. V.) as calculated to induce a cancerous degeneration of the ganglion. At the present time the seton might be made trial of under a form less dangerous. One, two, three or four simple threads passed through the tumor, as has been said of *Erectile Tumors* and *Varices*, and withdrawn after the lapse of some days, would probably be sufficient to create a moderate degree of inflammation in the cyst, and to effect its resolution. But how could we then avoid one of two inconveniences, a purulent inflammation which would not be unattended with danger, or too slight a degree of irritation, which would prevent our succeeding? Without, therefore, absolutely condemning this remedy, we ought not to repose too much confidence in it.

### § IX.—Irritating Injections.

Irritating injections, though made use of by some practitioners, have, however, always excited some apprehensions when about to be employed for synovial cysts. The inflammation which it is proposed to excite by them, has been considered dangerous, in consequence of the neighborhood of the articulations. It is true that some accidents have resulted from them; that a woman on whom they were used and who came to the hospital of the Faculty in 1824, was seized with all the symptoms of a phlegmonous erysipelas on the dorsum of the hand, where the cyst was situated, and on a portion of the dorsal region of the fore-arm; but, I do not think that the subject has been sufficiently examined. The synovial cysts are *legitimate serous cavities*; [see note infra, where the propriety of thus

giving the name *serous* rather than *mucous* to the various *bursæ*, is well sustained. T.] Every thing leads to the conclusion that an irritating liquid would produce an adhesive inflammation there, as in the tunica vaginalis. Provided this injection was made through a simple puncture, and not pushed to the extent of tearing (*érailler*) the cyst, and of becoming infiltrated into the cellular tissue of the neighborhood, we cannot see what evil consequences would result from it. The phlegmasia thus produced under the skin, should it extend even to the articulations, is not comparable to ordinary inflammations, or such as are produced by the action of some internal cause or external violence. Perhaps, also, the irritating injections have sometimes been followed by unpleasant consequences, because of the quantity or nature of the liquid made use of. Certain it is, that the tincture of iodine, which may be introduced in moderate proportions into every serous cavity, and which seems to have the power of infiltrating itself, at least partially, into the cellular tissue, without producing gangrene, has hitherto enabled me to obtain a number of cures which, by their simplicity, have been moreover of the most encouraging description.

A man aged from 30 to 35 years, had on the dorsal surface of the tarsus a synovial cyst of half the bigness of an egg; I punctured it and drew out about two spoonfuls of a serous liquid. Two gros of tincture of iodine diluted, were injected in their place, and every thing went on with the same simplicity as in the operation for hydrocele. The same operation performed twice on ganglions of the wrist, once below the external malleolus, and in another instance on the dorsum of the hand, have been followed with the same satisfactory results. I have seen it fail, however, in a man who had a synovial ganglion on the dorsal surface of the foot; but here the cyst was filled with gelatinous matter, and the injection caused no appearance of inflammation or reaction. In conclusion, therefore, it would seem, that irritating injections, and especially tincture of iodine, should be employed wherever the cyst is of a certain volume, and is found filled with matters purely serous. I would remark only, that they should be punctured with a small trochar, and not with the bistoury, and that a certain quantity of the tincture of iodine injected should be left in their interior.

#### § X.—*Incision.*

Like all other cysts, synovial ganglions may be treated by simple incision. Fabricius ab Aquapendente had already obtained cures by this operation, which is also extolled by Portal (*Hist. Anat.*, t. II., p. 227) and Schmucker (*Bibl. Ch. du Nord*, p. 21.) Nevertheless, practitioners of the present day do not resort to it but with repugnance. All the dangers imputed to irritating injections, are equally applicable to this. It produces, in fact, one of two things: either the small wound immediately shuts up without causing inflammation, and then the tumor soon reappears, or the interior of the ganglion becomes inflamed and is transformed into abscesses, and in this case we have reason to fear the extension of the phlegmasia under the form of phlegmonous erysipelas to the sub-cutaneous cellular tissue of the neighborhood, and even to the articulations that are situated nearest

to the tumor. The force of these objections cannot be denied, and in this respect the incision is certainly more dangerous, without being more efficacious, than irritating injections. Without inflammation it cannot succeed; with inflammation it causes pus, and purulent inflammation, in the vicinity of the articular synovial cavities, is always a formidable phenomenon. I would not, therefore, employ this means but for synovial cysts of a small volume, and for those which in place of matters purely serous, are filled with substances of a gelatinous (*gélatiniforme*) and semi-concrete character. I nevertheless admit, that the simple incision sometimes succeeds, and that it is far from being always attended with the dangers of which I have just spoken. As for the rest, I should prefer, should I decide upon it, to divide the tumor through and through, rather than limit myself to incising it only on one of its points.

### § XI.—*Extirpation.*

The remedy which has the greatest certainty, and which in every epoch has engaged the attention of practitioners, is extirpation. There is no doubt in fact that it is the most positive resource, and which precludes all chance of a return of the disease when applied to synovial ganglions. Unfortunately it is a remedy which alarms most patients, one also whose employment is not always devoid of difficulties and which may involve serious dangers. Thus to extirpate a cyst of this description, it is necessary to lay it bare by a simple, a semilunar, a T, or a crucial incision, then to go through a delicate dissection in order to isolate it from the organs which surround it, and thus remove it entire. The operation may in consequence be long, painful and sufficiently laborious. There results from it, moreover, a considerably large wound, whose suppuration it is often impossible to prevent. Finally, by operating in this manner we run the risk of opening into the synovial and articular capsules, and thus paving the way for the introduction of purulent phlegmasia even into the interior of the joints. It is nevertheless true that the dangers of this extirpation have been greatly exaggerated. I have performed it four times on the dorsum of the foot for ganglions which were of the dimensions of the thumb in diameter, a French chesnut, (*marron*.) a large nut or the half of an egg. The cure in three of my patients was speedily accomplished. The fourth, who was a young girl of nineteen years of age, continued to be threatened with a phlegmonous erysipelas during the space of a week; but sanguineous emissions and topical emollients put a term to the accidents, and the cure notwithstanding was completed at the expiration of three weeks. I have removed similar cysts from the inner as well as the outer side of the knee. I have extirpated one also which was situated immediately above the head of the fibula. I have treated them many times in the same way on the dorsum of the carpus and metacarpus, and out of twelve or fifteen operations of this kind which I could enumerate at the present day, there is not one of them that compromised the life of the patient. After the example of Celsus and Paul of Egina, so also have Warner, Gooch, Eller, Schmucker, (S. Cooper, *Dictionary*, t. I., p. 526,) and Heister, (*Thèses de Haller*, t. V., p. 262, French translation,) related successes obtained by means of extirpation, an operation which

Chaumète, (*Enchiridion*, etc., p. 123,) and Friesse, (*Thèses de Haller*, t. V., p. 243, French translation,) equally eulogize. In 1800, says M. Champion, when I was studying medicine, I extirpated in a young coquettish woman, a ganglion of the size of an almond, situated on the extensor tendon of the middle finger of the left hand. An inflammation supervened and gave rise to three abscesses. After the cure the young lady retained a stiffness in the movements of the hand, and this lesson has taught me not to repeat the operation. Nevertheless, a young physician of my acquaintance, adds the same practitioner, has extirpated one of less size, also situated on the metacarpus, and which I refused to operate upon, preferring to wait until it should become larger that I might burst the cyst; but no accident followed the operation. Synovial cysts situated on the thumb, carpus and tarsus, have also been removed without danger by M. Pl. Portal, (*Clinica Chir.*, pp. 298, 301, 303, 307.) I would however remark, that I now regard it superfluous to dissect such tumors with so much care; that I arrive at the same result with infinitely less difficulty or pain to the patient by confining myself to opening or cutting freely into the whole sac, which I immediately fill with balls of lint to induce it to suppurate, and afterwards treat it in every respect as an abscess. The operation is then remarkably simple, and I have satisfied myself that it will obtain a cure as prompt and certain as extirpation of the cyst, properly so called. As to the *ligature*, it is unnecessary to repeat that pediculated synovial cysts only would allow of its employment, and that it would expose to more pain and danger than any of the operations which have been described, especially the irritating injections, without being attended either with their advantages or simplicity.

#### § XII.—*Recapitulation.*

To sum up, therefore, synovial ganglions when it is deemed advisable to attack them seriously, should be treated by topical resolvers when they are still recent; by temporary blisters when they are already of ancient date; by permanent compression where the blister and dissolving pomades are without effect; by crushing with the thumb or mallet where ordinary compression does not suffice; by sub-cutaneous puncture where crushing is unavailing or inapplicable; by iodine injections, by preference wherever they are practicable; and by large openings or the complete incision in cases that are most obstinate or complicated. So that I reject as useless or dangerous, extirpation, simple incision, caustics, the ligature, and even vinous injections.

#### ARTICLE V.—OSSEOUS CYSTS.

We find in the annals of science some cases of tumors composed of osseous shells, in other respects independent of the bones and periosteum, and containing matters sometimes concrete, at other times liquid. I have met with these tumors on the breast, scrotum and shoulder, on the parietes of the thorax, certain regions of the cranium, and on the face and limbs. M. Tassery (*Annales du Département de l'Eure*, pp. 219, 220, 1810,) speaks of a cyst with osseous walls, which was situated on the hand, and which contained

about two pounds of cartilaginous substance, and the exsection of which was effectually accomplished by means of a saw. The osteo-fibrous tumor removed from the cheek of a young man by M. D. Lassarve (*Cas de Chir.*, &c., p. 27), caused the wounding of the canal of Stenon, and appears to have originated in the salivary duct. M. D. Lassarve (*Ibid.*, p. 41, fig. 4) has also given the figure of an osseous tumor which was as large as an egg, and while disconnected with the osseous system, occupied the middle of the upper lip of a young man aged twenty-five years. It will be however when treating of tumors of the face and breast, that I shall speak of the operations applicable to this description of cysts. I will remark here only in respect to general rules, that excision and extirpation are the only operations applicable to such tumors; and that we ought consequently to proceed in the same manner for their removal as for the extirpation of a lipoma, lymphatic tumor, neuroma or hematic tumor. It is moreover obvious, that topical applications, the seton, compression, injections, and excisions, properly so called, could have no chance of success, and that before every other consideration the osseous or osteiform plates should be removed in their totality, if we expect to obtain a radical cure in patients who have these osseous cysts.

[One of the most remarkable *osseous* formations but *not* of this description, occurred in an old man aged about 75, a sailor, of tall and robust form, and a patient at the Seamen's Retreat while I conducted that establishment. He was of intemperate habits, and the result of his indulgence in this respect was one of those old *rum legs* or extensive œdematous ulcers on the calf and below, which served as a drain to his plethoric condition. In a fit of depression of mind he threw himself from the piazza of the third story of the hospital, and thus caused immediate death. In the dissection, besides various extravasations which it caused in the brain, *every rib* on one side was fractured, and on examining the diaphragm we found in its substance near the centre, a *circular osseous plate* precisely of the size and thickness and shape of a dollar, which lay in the same horizontal plane with the diaphragm and in the midst of its tissue, as if inserted or sewn into that part. It did not appear during life that this formation had in the least interfered with the respiratory functions. T.]

#### [CARTILAGINOUS AND OSSEOUS TUMORS.

*Mediastinal Tumors—Carcinomato-cartilaginous Tumors.*—An extraordinary case of this kind, and of which the specimens are preserved by Mr. Adams, and were by him laid before the Pathological Society of Dublin, occurred in the practice of Dr. Cullen of that city, in 1839 (see *Dublin Review*, 1840), in a woman aged 40, who had been married two years but was without children. She had had for some time great difficulty of respiration, with violent but *dry* cough, and especially paroxysms of suffocation at night. The bruits of the chest were normal. The left hand and face were œdematous, and the veins of the neck and face livid and distended during the violent paroxysms of coughing. In three or

four weeks the left arm, and then the right, and finally the lower limbs also became œdematous. Finally, she was obliged to sit up constantly to get breath, and the neck began to swell enormously and to become inflamed immediately above the sternum. Death soon followed, when there was found in the situation of the thymus, in the anterior mediastinum, an oval whitish tumor near three inches long, of a carcinomatous structure, and in some places cartilaginous and cerebriform, which tumor inclined at its largest extremity to the left, and was adherent in part to the trachea and arch of the aorta. The inclination of the tumor to the left causing it to press on the vessels of the neck and shoulder on that side, explained why the œdema was greatest in that region. The heart, aorta and pulmonary artery were sound; also the air passages and lungs, except that the latter were emphysematous, no doubt from the continued violent paroxysms of coughing. This instructive case shows the importance of tumors in the thorax as connected with the difficulty of diagnosing substernal and thoracic aneurisms and pulmonary disease.

A still more remarkable case of tumor in the anterior mediastinum was published the same year as having occurred in the practice of Dr. J. M. Neligan, (*Edinb. Med. and Surg. Journ.*, April, 1840,) in a man aged 21, who in April, 1838, was attacked with difficulty of respiration, cough without expectoration, slight pain in the chest, &c., as in the above case. Finally, a tumor showed itself above the sternum, and the symptoms became aggravated, with orthopnea, swollen veins of the face and neck, suffocating paroxysms, and cold extremities, ending in death in less than a month from the attack. The lungs, bronchi, and trachea, were, so to speak, perfectly sound, and also the heart and its vessels, and some transparent liquid was found in the pleural cavities. We perceive the thoracic viscera were sound, notwithstanding the tumor had the enormous magnitude of 14 inches in length and  $4\frac{1}{2}$  inches in breadth, and had filled the entire anterior mediastinum, with firm adhesions in front to the posterior side of the sternum, and behind to the pleura and pericardium, while above it crowded the thyroid gland upwards and had even contracted firm adhesions also as far down as with the diaphragm below, and had extended laterally on each side to the articulations of the cartilages with the ribs. This case still more strongly points out the importance of close discrimination in diagnosing morbid structures in the thoracic cavity.

*Cartilaginous Tumors of the Face and Scalp.*—But one of the most singular complications of tumors perhaps on record, is that of an unmarried woman, aged 52, as related by Mr. Ansell (*Medico-Chirurgical Transactions*, vol. XXV., London, 1842, 8vo. See also *British and Foreign Medical Review*, Jan. to April, 1843, vol. XV., p. 153, 154.) The disease first appeared when she was 14 or 15 years of age, and the greater part of her *face and scalp* was loaded with *solid tumors* of different sizes. Those on the scalp externally were of a very florid color, smooth, glassy, and denuded of hair, and varied in shape from a nearly globular, to an irregular, flattened spheroidal form; among them were a few perfectly round and of a violet hue. Some were sessile on broad bases, others suspended by

short thick peduncles. One of these latter was removed, and when divided showed a smooth shining semi-transparent texture of a very *pale pinkish hue* and of a *nearly cartilaginous* consistence. It appeared homogeneous except for a few vessels ramifying through it. The investing skin was much more vascular. Among those on the face were interspersed also a number of lenticular tubercles arising from hypertrophy of the dermis, and some also smaller which were follicular elevations. The tumors sometimes itched and were painful when pinched, but were generally free from uneasiness. At one time a few were extirpated, and subsequently Mr. Bryant *removed sixty at one sitting!* They were then not cartilaginous and could easily be enucleated. Within twelve months from the operation they were all reproduced. This most singular disease invaded finally the viscera, and a large tumor appeared to have formed in the abdomen, which was followed by ascites, anasarca of the lower extremities, and death. On examining the body the peritoneum was found opaque, but with a shining surface. “The *parietal portion* (says the account) *and the lining of the diaphragm were studded with myriads of tumors of various sizes.*” The fat of the great omentum was almost entirely absorbed, and its tissue sprinkled over with numberless granules. A large mass weighing almost two pounds was suspended from the anterior edge of the liver; it extended beneath the right lobe, displacing and depressing the gall bladder. It was of ovoid and irregular form, and of very firm texture. On dividing it the tints of the cut surface were extremely varied, green and greenish yellow predominating, while the centre was nearly white and almost cartilaginous, and exhibited radiating fibres and lobules of an indistinct cystiform aspect. Blood oozed on pressure from a good many red points, but the tumor could not be called highly vascular. The disease appears to have been hereditary, but was confined to the *females* of the family, who were also remarkably prolific. A pullulating diathesis and tendency to fibro-cartilaginous growths appears to have pervaded the entire organism.

Mr. Goodsir (Cormack's *Lond. and Edinb. Monthly Journal*, &c. Feb. 1843, p. 171,) has removed from the compact bone of the shaft of the humerus on its outer side, an enchondromatous tumor of the size of a billiard ball, which was lobulated and of compact cartilaginous texture externally, and had internally masses of exceedingly hard bone, imbedded in soft cartilage. It bore the appearance of similar enchondromatous masses found in the phalanges of the fingers. T.]

[GANGLIONIC, SEROUS, AND SYNOVIAL TUMORS AND CYSTS—BURSÆ  
MUCOSÆ ET SEROSÆ—IODINE INJECTIONS.

*Encysted Hydropic Tumors between the duplicatures of the Peritoneum cured by Iodine Injections.*—Not only has the successful treatment by *iodine injections*, as established by M. Velpeau, been generally adopted in Europe for synovial tumors or hydrocele, but also, so long as six years since, was boldly applied by M. G. Pagani, Surgeon-in-Chief of the Hospital of Novarre in Italy, (see *Annali Universali di Medicina*, Fasci 296, Agosto, 1841,

also *Journ. des Connaiss.*, &c., de Paris, Février, 1842, p. 84,) to *hydropic encysted collections*, which apparently existed between the *duplicatures of the peritoneum in the hypogastric region*. The case in question was that of a man from the country, aged about thirty-two, in whom a rheumatic fever of short duration and accompanied by much dysuria, and finally a sort of dysentery, was soon succeeded, in spite of copious bleedings, purgatives, &c., by the rapid formation of a large encysted tumor in the hypogastric region. An exploration by the cataract needle and trochar enabled the surgeon to draw off a small quantity of fluid very similar to that of ganglionic capsules, [i. e. *bursæ mucosæ*, or more properly *bursæ serosæ*, see remarks of M. Pétrequin under this head, *infra*, T.] which with an examination per anum, and the introduction of the catheter into the bladder, and evacuation of its urine, led to the diagnosis that the tumor was circumscribed by the enormously distended layers of peritoneum where it is reflected on the posterior part of the bladder and anterior portion of the rectum. The surgeon accordingly, keeping in view the analogy of tissues to the tunica vaginalis, and the cures he had obtained by injection of the alcoholic tincture of iodine in hydrocele, introduced into the abdominal cavity in question, by means of the canula and syringe, through the puncture he had previously made, two fingers' breadth above the pubis, and two inches to the left of the linea alba, a diluted preparation of the same material. A very moderate degree of warmth and reaction was felt by the patient, and in five days the tumor had entirely disappeared, followed shortly after by the cure of the dysenteric affection and perfect restoration of health. It would be worth while to ascertain how far this treatment could be employed with utility in ordinary ascites, ovarian dropsy, &c. We have already spoken of it (see Vol. I. and the present vol.) as successfully employed in the mouth of the sac in reducible hernia, after the taxis.

M. Pétrequin of Lyons, in an article on synovial tumors, (*Journ. des Connaiss.*, &c., de Paris, Juillet, 1842, p. 10, et sequ.) in passing a compliment on the labors of MM. Monro, Brodie, Ollivier, Lenoir and Velpeau, disapproves the phrase *bursæ mucosæ* as altogether capricious and erroneous. These tumors occupy serous, not mucous capsules, and he has marked their whole progress, from their inception as simple hydropical collections, through the several successive stages of sub-acute inflammation, hematocele, abscess, ulceration, chronic induration, &c. M. Pétrequin reverts to a treatise he had published many years since, that on *exsections of the lower extremity*, and again enforces the necessity of early exsection of the great trochanter, and saving of the leg before the exfoliation caused in that process, by inflammation and improper treatment or opening of the sub-cutaneous *bursa* situated over that prominence, shall have involved the coxo-femoral articulation; for lesions of which last there is reason to believe these implications of the trochanter from the disease in the superposed bursa, are too often mistaken. The more important does this advice become, because the affection of the trochanter produced in the manner mentioned, may extend to the joint itself.

In ante-patellar bursæ, (hygroma prérotulien,) M. Pétrequin has seen one of four inches diameter in the direction of the axis of the

limb, and three inches laterally, which had existed two years, and which Dupuytren himself had in vain endeavored to cure. These bursal tumors often result from traumatic contusions, and then contain bloody, grumous, and sometimes *fibrinous* matter, which latter M. Pétrequin considers the original cause (or nuclei) of foreign bodies about the joint, i. e. spontaneous or amphi-articular bodies.

These tumors, arrived at this condition, communicate, on pressing them, a sensation of movement, (*frémissement*;) leading to the idea of the existence of semi-cartilaginous corpuscles or of hydatids rubbing against each other, all which can be explained by the existence of fibrinous concretions, or the crushing together of sanguineous clots. (See M. Velpeau's remarks on these bloody tumors sup. and in Vol. I.) He places, erroneously, as we think, some reliance on resolvents, (such as muriate of ammonia,) and on compression, &c.; but where these fail, he has found, like M. Velpeau, a cure effected by iodine injections, and should the contents of the sac be solid, an incision becomes necessary.

M. Pétrequin errs also, as we know from experience, both in olecranian and ante-patellar bursæ, (see in this note below, and also sup. and Vol. I.) in supposing that *bursting* them by strong percussion will not succeed if they have existed over a year. It is the remedy, as we conceive, *par excellence*, and next to that comes iodine injections.

He remarks, with great appearance of sound practical reflection, that such *ante-patellar* hygromas, when they suppurate and infiltrate into the neighboring tissues, might well give rise, by the tumefaction they produce, to the supposition of an inflammation and effusion into the tibio-femoral articulation.

These *sub-cutaneous*, *cellulous*, *serous bursæ*, as M. Pétrequin properly considers synovial bursæ, so called, are found, or may in fact be *accidentally* produced over all osseous prominences where there is much traction and friction of the superincumbent tissues, particularly therefore, it might be added, near the articulations. He has seen them at the inner *malleolus* also, becoming ulcerated and forming there pseudo-mucous fistulæ, like those which may result from abscesses. Such are cases in point for the iodine injections.

Besides *tibial bursæ*, as those on the internal malleolus may be called, M. Pétrequin has seen also *fibular bursæ*, i. e. on the outer malleolus. In cases like one he saw, and which resulted in caries to the fibular extremity, he properly recommends exsection of this part, which can readily be done without implicating the joint. These fibular bursæ are not uncommon among *tailors*, from their habitual position while at work making pressure on the outer ankles.

M. Sédillot speaks of *calcanean bursæ* (i. e. at the heel,) as new, or at least as hitherto undescribed by authors. That they have long been familiarly known, is an undoubted fact, but in most cases probably confounded with corns, to which they bear a resemblance at first. M. Pétrequin has described them in his usual clear and condensed manner. The epiderm forms a blister or phlyctena, and the subdermoid tissue is thickened like a large flat callosity or corn, and separated from the parts below. From this space oozes a serous watery discharge, the parts becoming more and more inflamed and exceedingly sore and troublesome. He says ulcerations and impli-

cations of the os calcis might ensue if such cases were neglected. Tight boots are the common cause, and the bursa is probably then an accidental production.

A very similar affection, which is not uncommon, (and which I have several times seen under the great toe,) explains, M. Pétrequin remarks, the existence of a *sub-metatarso-phalangeal* bursa in this part. This I treat by poulticing at first, and after the reduction of the inflammation, careful excision horizontally of the horny plates down to the sound parts, when a strap or two of adhesive plaster firmly bound round the toe and foot inclusive, readily completes the cure.

M. Pétrequin has seen a bursa similarly situated under the little toe, and considers also that a *bursa* exists *under* the heel, also on the lateral portion of the metatarso-phalangeal articulation of the great toe, where he has seen them cause much pain and inflammation, ending in suppuration, and passing thence into *chronic induration* of the capsular walls, giving the appearance of an enlargement of the extremity of the metatarsal bone. These also, we think, are sometimes mistaken for corny callosities; though most probably a great number of corns or callosities so called, about the small joints of the toes particularly, are in reality enlarged bursæ, from pressure of tight shoes, and therefore more common in females. The lateral bursæ at the toe go by the name of *ognons* in France, (see Vol. I. and Vol. II., under Corns, &c.) *Soft Corns*, so called in this country, and which form between the toes near their commissure, and which from their position become less frequently indurated, are also probably natural or accidental bursæ, inflamed by tight shoes.

M. Pétrequin has seen an inflamed encysted lateral metatarso-phalangeal bursa on the great toe in a man, acquire the size of an egg. It was red and fluctuating, and seemed to involve the natural bursa which exists above, and the one also below the articulation. On opening it pus and blood were discharged, after which a cure was effected by iodine injections. In one case the matter evacuated was gelatinous.

We do not wonder that M. Malgaigne, (see 4th edition of his *Manuel de Méd. Operat.*, Paris, 1843, p. 113,) could not succeed by Sabatier's inefficient mode of rupturing these bursæ, by slow pressure of one thumb over another. Sudden and strong percussion, as with a bound book, noticed by M. Malgaigne, is the only sure mode of making this process successful. (See our remarks *infra*; also on the same subject in Vol. I. of this work.) Certainly this mode could not succeed where there is no point d'appui, as when these tumors, according to M. Malgaigne, are found, (though extremely rare,) between the os hyoides and thyroid cartilage. Where they are met with, however, on the dorsal surface of the hand over the interosseous space, between the metacarpal bones, as we have said above, it would not *even then* be difficult, as it appears to us, to crowd them on to the adjacent metacarpal bones, and burst them in this position.

M. Malgaigne's own process in fact is nothing more than the sub-cutaneous principle of M. Guérin, and M. Goyrand of Aix, &c.; i. e. he draws the bursa forcibly to one direction, makes a small sub-cutaneous puncture into one extremity of the sac, evacuates the sy-

novia or small cartilaginous bodies if they exist, and then with the blade of the instrument sub-cutaneously breaks down effectually the walls of the bursa, after which he makes for 10 or 15 days strong pressure with flat pieces of agaric and thick compressions, (loc. cit., p. 113, 114.) This process may undoubtedly answer where percussion fails.

In encysted tumors, developed in the cellular tissue, containing collections of serosity or other liquids of greater consistency, as pus, &c.. M. Rêcamier is in the practice (op. cit. Malgaigne's *Manuel de Méd Operat.*, 4th edition, Paris, 1843, p. 113) of evacuating a portion of the pus, &c., little by little, and replacing this portion by injection of warm water, until the walls collapse and adhere, in the same way as he does for abscesses by congestion.

M. P. J. Cabaret of Saint Malo, (France,) in a memoir on bursæ mucosæ, (*Journal des Connaissances Medico-Chirurg.*, Paris, Juin, 1844, p. 224—228,) after noticing the almost total neglect which had been evinced towards them until the time of Béchard, (*Additions à l'Anatomie de Bichat*, 1821,) states that these bursæ form a roundish (obronde) cavity, divided by imperfect septa, (coloisons incomplètes,) but without any opening; that in their texture they appear to be membranes, differing only from cellular tissue by being more condensed and composed of large laminæ (en grandes lames); their evident design being [like cushions or pulleys, T.] to give greater ease to the movements of the bones under the skin. For which purpose their homogeneous smooth surface is slightly bedewed with an unctuous mucilaginous liquid. Most anatomists concur in the opinion that they are less numerous in children than in adults, because their development depends on muscular movements. M. Velpeau has noticed them on both sides of the spine, on the malleoli, and on the outer, posterior, and middle part of the thigh. I have seen them also in one case (the result of syphilis) directly over or upon both the great trochanters, easily movable, elastic, somewhat painful, elliptical in shape, and thus buried deep under the muscles and aponeuroses, as hard to the touch as a stone, and of the size of a pullet's egg, but totally disappearing spontaneously under the proper internal remedies for the constitutional disease to which they appeared to owe their origin. They are most usually found accidentally developed in consequence of unreduced fractures and luxations, and Sir B. Brodie has seen one of great size in the case of a girl with Talipes Equinus, and which formed upon the part of the instep upon which she walked. (*Pathological and Surgical Observations on Diseases of the Joints*, London, 1818.) The excessive secretion from their internal surface may distend them into elastic tumors, truly *hydropical* in their character, as our author, M. Velpeau, in a recent valuable memoir, has very properly considered them. (*Recherches Anatomiques, Physiologiques et Pathologiques sur les cavités closes, naturelles ou accidentelles de l'économie animale*, 1843.) Others have on that account invented for them the name of Hygroma, which is adopted by the writer, M. Cabaret, whose treatise we have under consideration. M. Cabaret remarks that these serous bursal tumors are found in all parts of the body, but more especially at the elbow, [see notes on this subject in Vol. I. and inf.,] the

knee, [vide same notes, T.] in front of the patella of individuals who rest frequently upon this part, such as preachers, religious persons, washerwomen, slaters, tilers, thatchers, &c., &c. In England, from the more rigid division of society there for centuries into certain casts or permanent occupations from one generation to another, more opportunities of course present for noting what may be considered the accidental products or results of such professions or occupations. Hence we hear there, and see surgical descriptions of these enlarged bursæ under the familiar names of the *miner's elbow*, the *housemaid's knee*, and the *scrivener's pahn*, &c. Sir B. Brodie has known this disease to be hereditary.

These tumors are, as might naturally be conceived, more or less dense or elastic, more or less distended, and of greater or less volume, according to the greater or less pressure, constriction, motion, &c., of the surrounding parts. While not in a state of inflammation, the contained fluid continues to be analogous to synovia; when arising from contusions, blood may be effused, giving a reddish or brownish or black color to the synovia. They then may be said to constitute a natural *hamatocele*, the same as happens in the cavity of the tunica vaginalis testis, or as some now call it *peri-testis*, in which case they present the most favorable circumstances for M. Velpeau's treatment of bloody tumors by percussion, [see Vol. I. supra,] or puncture and iodine injections, more lately advocated by our author. [See sup.] Fibrinous clots, says M. Cabaret, or a sort of transparent *bouillie*, are sometimes the result of the alterations which the blood undergoes in these tumors. At other times the liquid they contain is mingled with a number of movable bodies of a flattened oval form and deep-brown color, and in appearance resembling melon seeds. These small masses, which are at first albuminous and movable, progressively acquire a great degree of hardness.

M. Cabaret rejects every kind of local application, of frictions, lotions, unguents, &c., whether iodine, mercurial, saturnine, or otherwise, and also doubts the value of compression and temporary blisters, which have succeeded with M. Velpeau.

Excision of the tumor in whole or in part is also generally proscribed. M. Velpeau has seen two cases of death from this operation, (see *Archives Gén. de Méd.*, Paris,) and Mr. Keate has seen the disease return in a case in which he believed he had thus extirpated it. Sir B. Brodie recommends it only under certain restrictions or qualifications, which according to M. Cabaret are where the bursa has become fibrous, thick, disorganized and incapable of resuming its normal condition.

Simple incision is of no avail, as we all know, against a return, and the consequences, such as intense inflammation of the surrounding tendons, sheaths, and muscular tissues, abscesses, phlebitis, &c. are often of the most formidable character, which are likely, as we consider, to be aggravated by the former practice of introducing a seton into the cavity thus opened. This mode of provoking agglutination of its walls we deem too severe, of which opinion we find also M. Cruveilhier.

Puncture of the hygroma and injection of a moderately stimulating liquid, as for example, the iodine injections which have proved so

successful in the hands of M. Velpeau, is, according to M. Cabaret, deserving of adoption as a general method of cure for this disease.

M. Cabaret, in illustration of the success of this treatment, presents five cases, four of which were bursal tumors on the patella and one on the olecranon, and all of which were perfectly cured by puncture and injections of wine and water, diluted tincture of iodine, &c., causing in a few days complete agglutination of the walls without any serious degree of inflammation. We should suppose that for the puncture an extremely delicate trochar, not much larger than an exploring needle, would be most advisable, rather than an ordinary trochar or bistoury.

In conclusion, M. Cabaret says: The three last cases (two of the patella and one of the olecranon, and in which he injected the iodine) which I have just given, and many others which I possess, furnish incontestable evidence of the truth of the law laid down by M. Velpeau, in the following terms: that "we should cause to be produced in shut cavities containing effused fluid, an irritation which should be constantly *adhesive* and never *purulent*." These cases, adds M. Cabaret, will, I trust, help to make us feel the value to be derived from the treatment of hydropsy of the sub-cutaneous synovial bursæ by *iodine injections*, as administered according to the method of the learned professor of clinical surgery at the Hospital of La Charité.

Nevertheless, as we have before expressed ourselves upon this subject in various places in the text of this work, we must with all due deference to the importance of the facts above adduced, and of the unquestionable value of the treatment proposed and so successfully pursued by M. Velpeau, confess that we should in all cases where it is practicable, and where there is but little or no serious pain or inconvenience in the tumor, be the tumor of what size it may, (provided it has not, from its long standing, undergone the kind of fibrous consolidation spoken of,) prefer *sudden and powerful percussion*, as we have described it.

The distended, rolling bursa is then instantly broken up into fragments, if the stroke is made from a considerable height and with great force and rapidity, as by a heavy book or something similar. held in the operator's hand, while the patient is unaware of your intention and has his head turned away, and arm or leg firmly supported upon a table. Thus have I perfectly succeeded in a large olecranal *bursa*, which had been growing for a year or more in H—, a healthy mulatto (part Indian and part white) of sound constitution and good habits, and aged about 35. The patient, who was confidential porter of a distinguished mercantile firm of this city, finding the tumor at length had attained such dimensions, being oval shaped and of the size of a small hen's egg and exceedingly tense, though elastic, as to give a considerable degree of pain and annoyance in the use of his arms in hoisting and carrying boxes and bales of goods. He had imagined his arm would have to be *amputated*, and having promised, if it should be found necessary when I should examine it, (for I had not yet seen it,) that if so serious an operation as amputation was required it should be performed, I sent word to him to call upon me, and in that event I would give him a note to an eminent surgeon, who would do it at his clinique at

the University. Immediately on looking at it I perceived it was nothing more than a bursal tumor, and as there was nothing to prevent proceeding at once to the mode of cure I have mentioned, I asked him to stretch his arm out in pronation firmly upon the table, and to turn his head away. Having at this time purposely in my hand a heavy quarto volume which I appeared to be engaged in perusing, I suddenly came down upon the enlargement with it, holding it in both my hands, with all my force, from an elevation of three feet, striking such a blow upon it as dispersed in an instant every vestige of disease. To the patient it naturally seemed *marvellous*; and in fact would have appeared to be such in the eyes of most persons out of the profession. If an operation of this kind, so instantaneous, so bloodless and painless too, it may be said, (for the pain is but momentary,) and yet so radical in its total extirpation of the disease, was known to the school of Esculapius, we cannot wonder why the ignorant, marvel-loving, superstitious multitude, before whom this master spirit could have turned such skill to a valuable account, (by momentarily taking the patient for a few instants out of their presence,) should have deemed him more than mortal, and built altars and temples to his honor.

Far be it from the writer of this, however, to glorify himself on such an achievement, so long as its common utility and the facility with which any person may perform it, are so obviously sustained on the plain principles of common sense.

The truth and efficacy of this treatment, and its total protection from all return of the disease or any accident whatever, had been made manifest to me many years since, during my residence at Nassau, in the Bahama Islands, in effecting the same results for bursal enlargements upon the *wrist*. Besides the remarkable case of that on the olecranon just mentioned, I have since performed the same operation on another patient, also a laboring man, and on whom the tumor was situated in precisely the same locality; but in this last patient, from not having had it in my power to strike a full and perfect blow at first, I was obliged to repeat it a few days after, when the cure was complete, and has remained so now in both the individuals (whom I am frequently in the habit of seeing) for several years.

In another case there was a hemispherical sub-cutaneous bursal tumor of great size on the patella, full equal in dimensions to the half of a large orange, and completely covering the patella like a large inverted cup. This man, as the porter or wine-marker of a wine vault in the largest hotel in this city, was in the constant necessity of being upon his knees. I effected a partial cure and subsidence of the tumor for a year or more by producing, by means of common strong ammoniacal liniment, a copious suppurating drain over its whole surface for weeks; but ultimately was obliged, about three years since, to come to *percussion*, which was performed as mentioned, and which effected, as he informed me within a few months past, a radical and permanent cure.

It is unnecessary, perhaps, to say more than we have already said in the first volume on the new mode of curing bursal tumors by breaking them down (as in couching the lens in cataract) at the point

of a narrow tenotome, introduced sub-cutaneously at some distance from the tumor. The cures effected by this process, appear to be well substantiated, (vid. Vol. I.) and we have had no evidence (at least no published evidence) of its failure in any case. *A priori*, however, it would be deemed an operation of too great severity, but for these successes, and others of a more remarkable kind, by the same process, in extracting foreign bodies from the knee joint, and the practicability of which M. Velpeau himself has recently confirmed (vid. Vol. I.) by the sub-cutaneous extraction of a ball from the same articulation.

The successful treatment of enlarged *bursæ mucosæ*, by injections of *tincture of iodine*, as some years since introduced into practice by the learned author of this work, M. Velpeau, has, we are gratified in perceiving, been recently verified in a most satisfactory manner, by experiments performed for the same disease in horses. At the sitting of the Academy of Sciences of Paris, March 24, 1845, (see *Gazette Médicale* de Paris, Mars 29, 1845, tome XIII., p. 204, 205,) MM. Thierry and Leblanc communicated the result of their experiments upon this subject, made in presence of MM. Velpeau and Rayer. It is known, say MM. Thierry and Leblanc, that horses are often affected with dropsy in the articulations and mucous passages (*les courses muqueuses*), and which are described by veterinary surgeons under the name of *wind-galls* (*molettes*) and *vessigons*. Up to the present time, one remedy only has been employed for this affection, namely, the red hot iron, applied either in the shape of the rayed or the pointed cauteries. But whatever were the means used, injurious traces of the disease always remained behind. It was with the view of obviating this inconvenience, that the authors, guided by the researches of M. Velpeau, made experiments with iodine and vinous injections as compared with the application of the hot iron. From the results they obtained, they believe themselves authorized in declaring that iodine injections in the mucous *bursæ* and synovial sheaths, in horses, may advantageously replace cauterization by the red hot iron, and that in a plurality of cases, this mode of cure ought to be first employed.

We have upon the strength of well-attested recorded facts, considered the discovery of the mode of effectually curing these ancient *opprobria*, by the new system of *sub-cutaneous puncture*, so important and valuable, that we have been thereby in some measure compelled to anticipate our author in the position to which he has assigned this subject in the French edition of this work. As the cure of these bursal tumors, which have hitherto so much annoyed, as well as baffled, our art, except where the patient and surgeon together, have had the courage to adopt the ancient, and after all, when the case warrants it, the most radical process, (we mean *sudden percussion*), is the most important point to be considered in relation to them; we have, in consequence, said most of what we had to add on that subject, under the head of sub-cutaneous surgery, in our first volume. Though incisions and setons in these natural *bursæ*, enlarged morbidly into painful encysted sacs, (the most inconvenient cases of which are those in working men, as those familiarly known in Eng-

land, as the *maid-servant's knee*, the *miner's elbow*, and the *scrivener's palm*,) have been for the most part abandoned for the tenotome, several surgeons, nevertheless, among them our author, M. Velpeau, continue to adhere to his process. M. Velpeau's mode consists in a simple puncture with the trochar, to evacuate the *hydatid corpuscles*, which step is deemed indispensable to the cure, after which he makes use of free injections of diluted tincture of iodine, after the present received mode of treating hydrocele, in order to stimulate the sides of the sac to agglutination. M. Velpeau has met with most signal success by this course, and obtained speedy cures, free from all accidents. (*Ann. de Therap.*, Paris, April, 1845—also Cormack's *Lond. and Ed. Month. Journ.*, June, 1845, p. 460, &c.) M. Chassaignac (*Ibid.*) in a remarkable case of one of these tumors in the wrist, found that from its great size, twice that of an egg or orange, it was compelled by the annular ligament of the wrist to assume a *bilobate* form, about one half being above the ligament, and the rest in the palm of the hand. The large quantity of hydatids evacuated by the trochar were found by M. Chassaignac to be true species of that enzootic class, possessing, as examined by the microscope, elastic, compressible, *vesicular bodies*, and not composed of those hard, albuminous concretions which are mistaken, he says, for them.

M. Gherini, surgeon of the great Hospital of Milan, (*Ib.* and *Annali Universali*, Jan., 1845,) saw also a *bilobate* bursal hydatid cyst on the posterior part of the *elbow*, though that has no annular ligament to explain this form, and cured it by incision, evacuating 52 barley-shaped corpuscles. The sac suppurated, but the cure was complete. Neither of the lobes of the bilobular cyst communicated with the articulation. We should for ourselves be adverse to the incision in any case except in one of extreme necessity, as, for example, where there was great extent of inflammation in the cyst and neighborhood, from bruises, injuries, &c., and then the knife should be withheld until general and topical depletion had reduced the violence of the inflammation and attending fever, if any, and that the distension of the sac by the contained synovial or hydatid matters had made it necessary. But a mere small sub-cutaneous incision in such cases, and sufficient to evacuate the contents, is a very different thing from an extensive dilatation of these cavities themselves, while they are in an uninfamed state. The incision practised in this latter state, from the exposure to the air of the peculiarly sensitive tissue of these bursæ, becomes itself, by the operation, the source of danger, whereas in the other case, it is to subdue inflammation, that we have recourse to it. We think we are warranted by the pathological discoveries of sub-cutaneous surgery, and by the reiterated injunctions so studiously enforced by our author throughout this work on the subject of the dangerous accidents, such as burrowing, destructive suppuration, phlebitis, purulent infections, tetanus, typhus, &c., from wounding synovial membranes, surfaces, passages (*coulisses*) and capsules, to lay it down as a precept, that these bursal cysts must not be thus meddled with by direct incisions, except under the circumstances mentioned.

Irrelevant and improper as would be the admission into a work eminently didactic and elemental as is this on operative surgery by M. Velpeau, of all matter purely controversial, unless as in the academic discussions upon tenotomy (see Vol. I.) and those on fibrous tumors, (see this vol. *infra*.) new and valuable facts are thereby elicited, we deem it, nevertheless, an act of impartiality to state in this place, in reference to a subject already treated of in the 1st vol., (the sub-cutaneous puncture for articular dropsies and foreign bodies, &c.) that M. Bonnet, of Lyons, claims the merit, how just we cannot at present decide, (see his recent work, *Traité des Maladies des Articulations*, 2 vols. in-8° Paris, 1845, also a notice of the same in the *Gazette Médicale* de Paris, Mai 17, 1845, t. XIII., p. 319,) of having been the first to employ, and before M. Velpeau, *iodine injections* into the articulations. By a curious coincidence, however, M. Bonnet himself, in making this reclamation over the surgeon of La Charité, has in his work just cited, committed an act, (*Introd.*, p. xxxvi, and tome I., pp. 451, 487,) according to M. H. Diday, (*Gaz. Méd. loc. cit.*, p. 320,) of positive injustice towards M. Jules Guérin in another matter appertaining to this subject; viz., in asserting that we owe to M. Goyrand, of Aix, the credit of having first treated the evacuation of articular dropsies, and the extraction of foreign bodies in the joints, by the sub-cutaneous puncture. M. Diday contends (*Gaz. Méd.*, loc. cit., p. 320,) that at least the germ, or original idea of this treatment, in both these classes of affections, was so specifically and formally laid down by M. Guérin, as early as in the years 1840 and 1841, (see M. Guérin's *Mém. sur les Plaies Sous-cut. des Artic.*, lu à l'Acad. des Sciences de Paris, le 4 Mai, 1840; and the *Essais sur la Méthode Sous-cut.*, Paris, 1841, pp. 84 et 113.) that there can remain not a shadow of doubt as to his (M. Guérin's) claim of priority. M. Diday, however, seems willing to make a sort of commutation of this last mentioned difficulty, by admitting that M. Bonnet may possibly be entitled to the merit of having been the first to *execute*, and *with success*, the *sub-cutaneous* operation for the extraction of intra-articular foreign bodies; but that the same operation as applied to the evacuation of the liquid of hyarthrosies, by making this fluid pass under the skin, by a sub-cutaneous incision into the synovial capsule, as practised by M. Bonnet, is not so 'certain and efficacious a cure as the pure and simple evacuation of the liquid, by means of the syringe, as practised by M. Guérin; the process of M. Bonnet incurring the risk of not procuring a complete evacuation, and of leaving a portion of the liquid, as an irritating substance, under the skin.

*Patellar bursæ*, or those between the patella and integuments, and familiarly known in England as the *housemaid's knee*, may, Sir B. Brodie is satisfied, be reproduced after their complete extirpation, as he has frequently found to be the fact. (*London Med. Gazette*, May, 1846, p. 829, from Sir. B. Brodie's Lectures on Pathology and Surgery).

*Sanguineous Tumors treated by Ecrasement*.—The process of crushing, which we have felt it our duty to advocate in such unequivocal terms, as the one which should always be preferred, where practicable, for mucous bursæ, has been applied with eminent success,

also, in sanguineous hematic tumors that are external, and favorably situated for percussion. M. Velpeau reasoned very naturally, (*Traitement des Tumeurs Sanguines par écrasement; Annales de la Chirurgie*, Aout, 1843; *Arch. Gén.* 4e, ser., t. III., pp. 217, 218, 219,) that the extravasated blood of such tumors, if once dispersed by their rupture, so as to become infiltrated into the surrounding cellular tissues, must naturally from its assimilation to the great mass of the vital fluid, be absorbed with yet greater facility than the serous liquid of synovial bursæ. He also presents as another striking argument for the *écrasement* of such tumors, the fact, that left to themselves, in their semi-concrete and confined position, they are rarely absorbed, whereas every one is familiar with the fact that every ordinary ecchymosis or extravasation of blood from a blow or bruise, is rapidly absorbed, and for the reason, that in the latter case it is dispersed by the accident itself, into the cellular tissues. This, probably, is the source of the correct vulgar practice of applying pressure and friction immediately, and as soon as such bruises are received. The *écrasement* is performed by M. Velpeau by sudden pressure upon the tumor, with the palm of the hand or with the thenar eminence, or with both hands, or it may be done with a solid body, as a piece of money or wood, which is to be struck upon with a hammer or the fist. The tumor is broken up immediately, leaving only some lumps (*bosselures*) in the tissues. The tumors best adapted to it should not exceed the fist in size. He very judiciously adds, that a solid point d'appui must of course exist as in ordinary serous bursæ, and before the operation can be thought of. In case of an eschar on the tumor, the process may still be applied if the eschar is superficial, and has not begun to be detached; in the contrary case we should abstain. *Ecrasement* is better adapted to the effusions in accidental, than in normal close cavities, as the walls of these last are always thicker, and consequently more resistant. M. Velpeau furnishes numerous cases of cures in favor of this, as it appears to us, most judicious treatment. Surgery, it may be said, has at length obtained a tolerable mastery over external, synovial and hematic tumors, either by means of *écrasement* or sub-cutaneous injection of iodine, to say nothing of the value of this last, or favorite process of the author in normal close cavities.

*On Close Cavities in general.*—Before this chapter closes it is proper to insert in this place, and more in detail, the new and important views of our author, M. Velpeau, as published by him in his work, entitled *Recherches Anatomiques, Physiologiques et Pathologiques sur les Cavités Closes, naturelles et accidentelles, de l'économie animale*. (Par A. Velpeau, &c., Paris, 1843, pp. 208, see also an extended abrége of this in the *British and Foreign Med. Review*, vol. XVIII., July—Oct., 1844, pp. 79, 90.) M. Velpeau maintains the new proposition, that serous and synovial membranes, as distinct tissues, *have no existence*, and consequently that the notion of close cavities formed by such membranes, is entirely devoid of foundation. He bases this proposition on the facts obtained from intra-uterine life. From ten embryos examined by him, and which were from fifteen to thirty days old, he concludes that even up to the 4th week the free surfaces present no appearances of membrane; the whole body consisting

apparently, of a homogeneous, gelatiniform and fragile substance, none of the cavities any where being lined with any distinct membranous tissue, or laminae capable of being isolated. The whole is either *surfaces* or *parenchymata*, while there is nothing either in the head, chest or abdomen, to justify the expressions cutaneous, mucous and serous membranes, &c. He contends that what for example we call in extra-uterine life the peritoneal or serous membranes do not always exist, and cannot be detached as a distinct peritoneal or serous membrane, properly so called. They are in fact only *serous surfaces* continuous with, and not separable (except by a traumatic division) from the subjacent cellular parenchyma of the organ, as on the liver, uterus, ovaries, &c. So behind the linea alba. In proof of this, it is to be considered that the *serous membranes*, properly so called, do not exist, and do not become manifest until at a very advanced period of the embryonic state, that is, prior to the organs invested by them. Pursuing the same course of reasoning in respect to other cavities than those of the abdomen, and which, however ably maintained, is too strictly pathological to be properly embraced in the text of our work, M. Velpeau comes to synovial cavities, properly so called. He shows that there are but few vestiges to be found of this supposed serous membrane. Thus, in the knee it is no where to be found, on the free surface of the cartilages, or on the internal surface of most of the ligaments.

*Accidental close cavities* are divided by our author into functional and pathological. The functional consist of: 1. Serous cavities 2. Articulations; and 3. Cellular cavities. The first, or *serous*, are formed by an ovary, a noose of intestine, or a knot of epiploon or other viscus passing through a fissure of the peritoneum and abdominal muscles, so as to fix itself under the skin. The second or *articular*, are connected with the articulations, and caused by a luxation or fracture. They have no lining membrane, and are nothing more than the polished surface of the textures which enter into their composition. The third or *cellular* cavities, are those usually denominated synovial or mucous bursæ, and are accidental sub-cutaneous arrangements, which nature interposes over any projecting point or surface of bone which is exposed to much pressure from without, and are evidently designed to protect the soft parts from the hard, in the nature of pulleys, or rather a sort of distended sacs or air cushions. Thus on the backs of porters and on the acromion of persons who carry burdens on the shoulders, on the angle of the scapula in those who carry scuttles, &c., on the anterior part of the sternum in joiners, &c., on the malleoli, [and tuberosities of the ischium, T.] in tailors, &c., on the hump of humpbacks, and on the salient points of club feet. To these we may specify those which in certain occupations in England are so common as to have acquired, as we have elsewhere frequently noted in this work, a particular designation. Thus the bursa over the patella, called the *housemaid's knee*, seen also in the other sex, and in all who have occasion to rest much on this part; so also the *miner's elbow*, meaning the bursa at the acromion, caused by the position in which the miner works. To these add the *scrivener's palm*, or bursa in the palm and wrist of those who have to write a great deal. Our author also has seen them on the body of

the clavicle, on the posterior surface of the fore-arm, on the internal surface of the tibia, the crest of the ilium, &c., from exposure of those parts to friction and pressure. All these cavities, like normal ones of the same character, are destitute of investing membrane.

*Pathological close cavities* comprehend every kind of abscess, cyst, and morbid deposit. But it is to *morbid sub-cutaneous close cavities*, analogous to the normal close cavities of joints and under tendons, that he particularly directs attention. These *sub-cutaneous morbid cavities* are observed: *a.* In the *cellular tissue*, which have been described particularly as serous cysts, and which are surrounded by the condensed cellular tissue, which is mistaken for a supposed lining membrane to the cavity; *b.* In *glandular bodies*, as in the thyroid body, breast, testicle, &c., where it is also clear that their surface is part of the tissue of the gland. The *pellicle*, which may occasionally be separated, has been formed there in the same way as that which constitutes a part of the cavity of an aneurismal sac, in which the blood has continued to circulate. In the ovaries, M. Velpeau says, the truth of his doctrine is strikingly illustrated by the coexistence of *real cysts* like hydatids and which can be readily detached from the tissue of the organ, with close cavities the surface of which is inseparable from it, and forms part of it. *c.* In *ganglial cavities*, as under the jaw in the region of the parotid, and in the carotid canals, and in front of the larynx, in the supra-sternal fossa, axilla, bend of the arm, groin, and ham, and in the interior of the pelvis. These last may exist in the gland, shut up, as it were, and with their sides in contact, or if they are towards the surface of the gland, they then, from having room, expand into a pouch, which, however, will always be found to be attached in some portion of it to the glandular mass. The practical inference from all the above is that *diseases of close cavities or surfaces* are in fact primarily nothing more than *diseases of the tissue*, of which these cavities constitute a part. From whence M. Velpeau lays it down as a law, that as the articular cartilages are destitute of arterial and venous circulation, and of a serous membrane, properly so called which is distinct from their tissues, so neither inflammation, ulcers, fungous diseases, nor transformations, nor degenerations of any kind, exist as a primary malady on the free surface of those articular cartilages. A deception may arise in this way; that inflammation without the cartilages may lead to a deposition of lymph between the cartilages, and this deposition becoming organized and vascular, or even blended with the surface of one of the cartilages, may give rise to the supposition that the free surface of the cartilage itself is the seat of the disease. For this deposition may constitute a real vascular movable membrane in the articular cavity. Hence fungosities and vegetations upon this membrane may be described as those of a synovial membrane. M. Velpeau admits that in the progress of the disease, the cartilage itself may now become implicated, and thus vascularized from its circumference to its central parts. This however, he says, is no proof of a real synovial membrane, as the friends of Bichat maintain, on the diarthrodial cartilages, or that inflammation ever originated on an isolated layer of such cartilages.

The opinion advanced, that articular cartilages are *unorganized*,

is, it must be confessed, contested by a great number of authors. M. Velpeau contends that the *synovial fluid* is directly produced from the surface of the articular cartilage. The salutary organic process of adhesive inflammation, deemed peculiar almost to cellular tissue, and seen as the precursor or protecting interposition intended by nature to circumscribe and to intercept the progress of suppuration, is developed also in close cavities, and with the greater rapidity in proportion as their parietes are smooth and completely serous, finally soldering them together and obliterating the cavity. This adhesive inflammation is dangerous in large cavities, as in the peritoneum and pleura, and may in its turn give rise to suppuration. The *excitation* therefore, where we wish to obliterate a cavity, as in hydrarthrosis, should, as before observed, be so controlled as to produce always an *adhesive inflammation only*, and one which shall never become purulent. The more the effused fluid resembles serum, the more easy is it to procure adhesive inflammation, and the more it resembles pus, the less chance is there of escaping purulent inflammation. Hence it is an important point to change the contained fluid as much as possible into the condition of serum, which our author maintains, can in certain cases be effected by frequently emptying the cavity by puncture. So also with accumulations of blood; and in this manner there is finally poured out instead of blood or pus, a purely serous, or a sero-sanguineous or sero-purulent fluid. This result M. Velpeau has verified in most regions of the body. This brings our author naturally to his favorite injections with iodine, as tested by him with such eminent success in hydrocele, &c., and the latest information in regard to which will be found at length in our notes under that head (*infra*). He remarks in this work under consideration, that additional importance is given to iodine from its well-known resolvent properties, and the beneficial influence which these properties may have upon the *infarcted condition* which is generally found to exist in some parenchymatous organ, in those cases in which there is a serous effusion in a close cavity. This applies directly to an infarcted or congested testicle accompanying hydrocele, and where M. Velpeau has found the true treatment to lie in a course which is the reverse of the old practice. Thus, therefore, instead of endeavoring to resolve the congested testicle before treating the hydrocele, he begins with both, and acts upon both at once by his iodine injections into the hydrocele cavity; that is, provided the infarction is not scirrhus, encephaloid, melanotic, or tubercular, but merely a hypertrophied condition of the testicle. The most fortunate results have been obtained by M. Velpeau by the practice in question.

But it is unnecessary to dilate here on the advantages of these injections, as we have given the latest details from M. Velpeau himself and others, (see this volume, *supra*) and (*infra*), as more fully disclosed in the recent animated discussion to which this subject gave rise in the Paris Academy of Medicine. It is proper, however, to notice the various kinds of diseases of close cavities in which M. Velpeau now successfully employs this treatment:—1. In encysted collections of serum in the tunica vaginalis. 2. Collections of serum in the tunica vaginalis, which communicate with the cavity of the

abdomen, forming what is called congenital hydrocele. 3. Serous collections within a perineal sac, whether the sac be continuous with the peritoneal cavity or otherwise. 4. Encysted serous collections of the spermatic cord. 5. Serous collections in the external genital organs of women, contained in close cavities, and resembling the last mentioned. 6. Serous collections in the lymphatic ganglia of the groin and iliac fossa; and 7. Collections of purely liquid blood in the interior of the pelvis in women. We wish we could subjoin additional successful results to the few well-authenticated cases we have alluded to in our first volume, in which the neck of the sac of several old, large, and reducible inguinal hernias, (not congenital,) has been completely and permanently obliterated, and the hernia radically cured by means of *injections of Tincture of Cloves*, (doubtless suggested by the practice of M. Velpeau,) in the hand of some young and bold practitioner of this country. But we are not aware that this practice has been followed up, though several remarkable cures to which both Dr. Mott and myself were both eye-witnesses, and the happy results of which gave much satisfaction to that surgeon, would certainly authorize new trials with it. M. Velpeau has succeeded with iodine injections in the cavity of a large sanguineous tumor, which was diagnosed and proved to be such by this distinguished surgeon, and which had formed behind the uterus and ascended towards the right iliac fossa. He also succeeded in a case of an accidental close cavity in the thyroid body, which though the first in which he found constitutional febrile reaction caused by the iodine, ultimately recovered. Finally, the same success has attended his iodine injections when thrown into the cavities of the joints, to cure articular effusions, and he had thus already triumphed (when this book was published, 1843) in six cases out of seven of pure hydrarthrosis. His experiments on dogs go to show that iodine of more strength than one-seventh of the water used to dilute it, is fatal when thrown into the peritoneal cavity; not however by absorption and poisoning, but by peritonitis and enteritis. The state of this question of iodine injections at the present time will be best understood by our notes elsewhere in this volume, (vid. infra.)

*Treatment of Tumors.*—M. Bonnet of Lyons, with all the natural predilections which an eminent surgeon like him must possess for the chirurgical rather than therapeutical treatment of disease, has in his late important work (*Traité des Maladies des Artic.*, 2 vols. in 8°, Paris, 1845: see a short critique on this work, by M. H. Diday, in the *Gazette Médicale* of Paris, Mai 17, 1845, p. 316 et sequ.) insisted very judiciously as we think upon the absolute necessity of looking to the general diathesis of the whole system as the frequent if not most common source of all fungoid, serous and other growths and diseases in the articulations. Some of his views upon this subject appear to be presented under an original aspect. The cause of these diseases lies, M. Bonnet says, most frequently in an *arrest of organic development*, dependent on the general condition of the system. Thus *articular fungosities* (fungous growths or tumors) for example, are nothing else than plastic lymph which has been suspended by an internal influence; the part which is the seat of the disease being but a type of what is passing in the general economy;

but if the vital energy in the latter, now temporarily paralyzed, should recover itself, these fungosities will be converted into fibrous (i. e. healthy organic) tissue. As in the serous membranes, so in the articulations, the fibrous transformation is the fortunate or salutary maximum or last term of the *nisus formativus* : and wherever a fibrous layer is found upon the articular surface of bones denuded of their cartilage, and that we perceive this tissue expanded into membranes, or concentrated into fibrous bundles (*faisceaux*) going from one articular extremity to the other, we may conclude for a certainty that there has been one step taken towards a cure, a *vis medicatrix* established by nature to complete the evolution of the coagulable lymph.

M. Bonnet makes three distinct classes in the products of secretion which are formed in diseased articulations : 1. Those which are systematically (*régulièrement*) organized ; 2. Those which are arrested in their organization ; and 3. Those which are not at all organized.

Thus the general diatheses, so clearly established in *arthralgias*, may be characterized themselves by their tendency to favor one or the other of these three products : in the less severe, as in acute or chronic rheumatismal diathesis, the tendency is to the first or effusions of plastic lymph ; in other cases, as in the scrofulous diathesis (where synovial fungosities are most frequently met with) a disposition will exist to the secretion of incomplete organic products ; in the diathesis which is still more aggravated, [i. e. where there is the greatest degree of degeneration in the organism, T.] as in the tuberculous, purulent and gouty, there are no organic products secreted, but depositions of tubercles, pus and uric acid, [rather lithate of soda either in a fluid state or in crystals, which depositions constitute gout. T.]

*Fungous articular tumors* are unconditionally ascribed by M. Bonnet to the scrofulous or so called strumous diathesis, of which he makes several species, altogether distinct from the products of the tuberculous diathesis, as well by their external appearance as by their peculiar characters.

He makes two distinct classes of scrofulous persons : 1. Those who are pale, thin and without any trace of tumefaction in the external glands ; such have also hollow cheeks, the eyelids and lips thin, complexion pallid, and frequently cold abscesses (*abcès froids*) without tubercles. These are individuals with the *purulent diathesis*. 2. The other class have the face full, the alæ of the nose, the lips and the eyelids tumefied, and the glands of the neck in general voluminous. They are disposed to congestions with mucous secretion, ophthalmias, otirrheas, &c. These are what are denominated pre-eminently scrofulous temperaments, but which M. Bonnet proposes to consider as laboring under a *fungous diathesis*, (*diathèse fongueuse*.) In them we frequently meet with local lesions, such as those fleshy soft masses, whose tendency is to suppuration and which are usually designated under the name of *fungosities*, (*fongosités*)—not only in the articulations, but frequently in the bones themselves, under the name of *spina ventosa* ; also in the glands, which thence become swollen, and in the nose and cheeks, where they may ulcer-

ate and become the source of phagedenic eruptions (*dartres rongeantes*), [as *phagedena* or *cancra oris*, T.] &c.

M. Bonnet has pointed out with much force, the injury done in the treatment by the common machines employed to keep the joint in a constrained and vicious position, whereby the disease, from a false idea of obtaining repose for the limb, is greatly aggravated, the synovial membrane and ligaments on one side kept in a state of tension, the osseous surfaces compressed on the other, with a permanent tendency to an alteration in the natural relations of the bones. He had by various experiments on the dead body, to determine the best possible position for the articulations, contrived a number of kinds of ingenious apparatus based upon these objects: 1. To bring the limb into such a position that no stress is made on the synovial membrane and ligaments, that no danger is incurred of spontaneous luxation, and that will allow (as in cases of ankylosis) of the easiest exercise to the limb; 2. To retain the part in this position during a greater or less length of time, as may be required to complete the cure.

Among other remedies of a local character, M. Bonnet has derived great advantage in articular diseases from *transcurrent cauterization* with the red hot-iron, frequently repeated, eight or ten times for example, on the same scars—also from the *moxa*, for which purpose he prefers the large *Egyptian* moxa.

*Double Encysted Tumor*.—Dr. W. L. Atlee, of Lancaster (Pennsylvania), gives a very interesting account of the successful removal, by him from a healthy, robust boy aged four years, of an enormous spherical double encysted congenital tumor on the right side of the trunk, which overlaid several of the lower ribs and the abdominal muscles on that side, encroaching even upon the internal abdominal ring. It was closely adherent by a broad base to the tissues mentioned. On making a long incision over it in the direction of the fibres of the external oblique muscle, he finally succeeded by a tedious dissection, rendered the more so by the obliteration of the sub-cutaneous cellular tissue, in extracting the entire mass. This was found to consist of two distinct hemispherical cysts, one within the other, and both filled with serum, the intervening space between the two being filled up by small oval hydatid-like cysts containing pink-colored serum and which communicated with each other by narrow necks. Tough fibro-cellular aponeurotic bands ran over the inner surface of the two principal cavities and connected the whole structure firmly together, giving it the appearance of the interior of the ventricles of the heart. (*Amer. Journ. Med. Sciences*, vol. VII., new series, Philadelphia, 1844, p. 84–88.) T.]

## CHAPTER IX.

## FIBROUS TUMORS.

Among the concrete tumors which remain to be spoken of, I have a word to say of those which are known under the name of fibrous tumors ; not that I propose to treat now of *polypis* under this name, (de ce nom,) but of tumors which appear to originate from a concretion of lymph or effused blood in the tissues, or from a transformation or limited hypertrophy in some circumscribed part of the natural tissues. These tumors, which are ordinarily globose, (globuleuses,) though more or less bosselated, are hard, elastic, indolent, and of a grayish color and of a fibrous and mammellated structure. Some excavate for themselves a species of cyst in the tissues, the different layers of which latter they flatten out (étalent) and compress ; others are blended so intimately with the surrounding tissues that it is impossible to separate them from these by enucleation. I have seen some tumors of this kind which had acquired the size of the head of an adult, and it is rare they are found of much greater dimensions except in the interior of the pelvis ; most usually they do not exceed the volume of a small nut, or that of an egg or the fist. As they occasion no inconvenience in themselves, they may exist during life without any real danger to the patient. As they are, moreover, wholly incurable by any other mode than by extirpation, it is imprudent to meddle with them, unless by their volume, weight or position they occasion some actual trouble or disturbance in the economy, or too great a degree of deformity.

## § I.

To effect their separation by a ligature would not be possible or at least not advisable, but for such as had a sufficiently narrow pedicle or neck at their union with the skin. In regard to this. I have only to refer to what I have said of the ligature for tegumentary tumors, properly so called.

## § II.

When we have decided upon extirpating them, we have scarcely else than to recall the rules for the extirpation of fatty, rather than those for lymphatic tumors. As they are generally disconnected with any kind of constitutional affection, and constitute almost always a disease purely local and separate from and independent of all the natural tissues, and represent, in a word, a simple foreign body in the midst of the organs ; a fibrous tumor may be extirpated with every degree of security, and without the necessity of removing with it a large portion of the sound parts. Being rarely liable to return, and leaving a wound which is pliant (souple) at the bottom, and destitute of any dangerous germ, we are enabled after effecting their ablation, to undertake immediate reunion with every possible chance of success. What I have just said, however, is applicable only to those

fibrous tumors which have, so to speak, dug out for themselves a cyst in the midst of the cellular tissue. In fact, in respect to the others, it would be impossible to isolate, and preserve the skin which covers them. There are in fact some which, under this point of view, would lead to unexpected embarrassments if we attempted to operate upon them by the ordinary methods. A porter who had upon his nape a fibrous tumor of the size of the fist, came in 1831 to the hospital of La Pitié to have it removed. This tumor was movable, with a large base, indolent and devoid of any change of color upon the skin. With the view of laying it bare, I made a crucial incision upon it, but soon discovered that there was no limit between its tissue and that of the skin. It consequently became necessary to cut out the four flaps in their whole extent at the expense of its external surface; and when I had extirpated it, I was enabled to ascertain that it was continuous at all its points with the tegumentary tissue, of which it seemed to be nothing more than an inflated (*raréfiée*) layer enormously hypertrophied. The operation was followed by no serious accident; only that the skin in the neighborhood continued hypertrophied after the cure of the wound, so that the patient remained almost as deformed as before the operation. I have since seen two instances of similar tumors, one at the nape and the other at the middle of the back. A third fell under my observation in November, 1838. A man 45 years of age had on the median line, or a little to the right of the anterior half of the cranium, a tumor which at its point descended down to the forehead, and was prolonged upwards to a line with the parietal protuberance. This tumor which had formed gradually and without any appreciable cause, and which appeared to be situated upon an incipient exostosis, had perhaps like the preceding been produced by the repeated frictions to which the diseased region had been subjected, and was moreover movable, without any well-defined limit, and in every respect indolent. In whatever manner it was attempted to displace it, it was always possible to recognize in it a disc or plate of integuments excessively thickened or distended, with an entire absence of degeneration or transformation of tissues. But for fibrous tumors being unaccompanied with this last feature, I should in fact deem those of which I speak a species of flattened elephantine tumors of very limited extent.

It follows from these remarks, that in order to effect a perfect cure, it is necessary to remove at the same time with the tumor, every portion of the skin which is adherent to it or constitutes a part of it. In the three last cases therefore I have just mentioned, I refused to operate, inasmuch as extirpation is not in my opinion justifiable, but for those tumors which continue to increase, or which become the source of serious accidents. Some other fibrous tumors, which also include the skin in their composition, are however distinguished from the preceding in these particulars, viz: that well-defined limits soon become established between them and the sound tissues, that the elements of which they are constituted are no longer in a normal state, and that they seem susceptible of dangerous degenerescence and transformation. A man of about 50 years of age, and who came to the hospital of the faculty in 1825, had in his right groin a tumor of this

description, which was of half the size of the head, and extended obliquely from a line with the vessels as far as to the posterior part of the thigh below the scrotum. It was extirpated by M. Roux, and we found that the entire tumor was homogeneous, and formed of a tissue, the section of which presented some analogy to that of Gruyère cheese. The patient got well, but in the following year there returned a similar tumor, which was also extirpated; without however preventing him from succumbing at a later period to the effects of a schirrous tumor which formed on the front part of the pubis. As to fibrous tumors, which are independent of the skin, they may be developed upon almost all the regions of the body and especially in the sub-cutaneous tissue. In a woman operated upon successfully by M. D. Lasserre, (*Cas de Chir.*, etc., p. 17, gg. 1. Perigueux,) he was enabled to extract a fibrous tumor of twice the size of an egg situated upon the upper lip, in such manner from the midst of the tissues as to leave but very little deformity. A patient in whom M. M'Farlane (*Encyclop. des Sc. Méd.*, 1833, p. 56,) had removed a fibro-cartilaginous tumor which was situated upon the side, between the transverse and oblique muscles, died of peritonitis in the course of 31 hours. A young lady on the contrary who had above the crural arch, a fibrous, movable tumor, of the size of a small egg, recovered perfectly from the operation which I had recommended to her, and M. Yvan junior has communicated to me a similar fact. A patient who had one of the size of a large nut on the dorsum of the metatarsus, came to have it extirpated, at the hospital of La Charité in 1836. Having divided the integuments by a simple incision, I seized the tumor with an erigne and proceeded immediately to its removal. The consequences of the operation were simple, and the tumor did not reappear. Another patient operated upon in 1837 at the same hospital, for a tumor in every respect similar, and which was situated two inches above the external malleolus, between the tendo achillis and the fibula, was cured in the same way. I have removed from the breech of an adult man a fibrous tumor as large as an egg, which did not go deeper than the aponeurosis and was never reproduced. Another patient whom I operated upon in 1835, had one of the same nature between the anus and tuberosity of the ischium. The cure of this also was radical. But a woman who had one of these tumors on the dorsum of the point of the sacrum, and which adhered throughout its deep-seated surface to the periosteum, thus rendering its dissection sufficiently delicate, was seized with an ichorous suppuration, caries of the pelvis and general accidents, which caused her death at the expiration of a month. Tumors of this description which I have met with in the breast or the head, will be referred to again in other articles. I will merely add that whatever be their situation, if the skin which covers them shall be found too much attenuated or actually degenerated, it will be advisable to remove an ellipse from it or take it away entire at the same time as the tumor, rather than attempt to dissect it. A young girl of eleven years of age had on the radial and dorsal side of the root of the middle finger, a hard, bosselated, blackish-looking tumor of the size of a large nut. With this tumor, which I isolated from the hand while respecting the metacarpo-phalangeal

articulations and neighboring extensor tendons, I removed also a flap of integuments one inch in length and six lines in width. A strong and robust man had, from the age of 20 years, above the outer malleolus, a globular and very movable tumor covered with attenuated reddish-colored integuments. Having seized this tumor with an erigne, I circumscribed it in an ellipse of the skin, and removed the whole of it while dissecting its deep-seated surface. By this mode, the operation is prompt and certain, and ought to have the preference when it does not cause too great a loss of substance. With these exceptions, fibrous tumors must be submitted in every respect to the rules of treatment indicated for lipomatous tumors.

---

## CHAPTER X.

### CANCEROUS TUMORS.

All the tumors of which I have hitherto spoken, come within the class of tumors denominated *benignant* by the English surgeons. Those on the contrary designated under the title of cancerous tumors, have a character of *malignity* which has always served to distinguish them from the others. Their tendency to repullulate and to multiply without end, has ever constituted them the opprobrium of surgeons. If they are attacked on one side, they soon reappear on the other. Frequently the most simple operation will be sufficient to irritate (*exaspérer*) them and aggravate all their symptoms; no method of treatment, even at their first appearance, can promise any certainty of effecting their radical cure. There are a great many surgeons moreover, who advise that we should do nothing with them, or make use only of palliative means. Nevertheless, upon the supposition that these tumors are primarily a local affection, and admitting also their malignant character, I lay it down as a principle to destroy them as soon and as effectually as possible. To me it appears evident, that if there is even room to hope for their cure, it must be by means of their mechanical or chemical destruction, and by attacking them before they have had time to introduce new morbid germs into the rest of the system. All the varieties of tumors however, denominated cancerous, do not exhibit the same tendency to repullulate. Those which in this respect should be placed at the head are the *melanotic* (*mélaniques*) tumors; then come the *encephaloid* tumors; *scirrhus* tumors would be placed in the third line, and the *colloid* at the bottom of the scale. These particularities, which I will discuss more at length while speaking of the extirpation of the breast, convey an idea of the course which the surgeon ought to pursue in regard to the prognosis and treatment of cancerous tumors in general.

#### § I.

Should the tumors be purely melanotic, composed of flocculi or clots of anthracine, we should avoid performing the slightest operation

upon them, provided there existed at the same time with the principal nucleus some spots or granulations of the same nature, either in the neighborhood or in other regions, even though the patient should in other respects appear to be in excellent general health. A man in other respects in good health, came in 1834 to the hospital of La Pitié for the removal of a melanotic tumor upon the temple, of the size of a large nut. This tumor, which M. Olivier of Angers had extirpated a year before, and which had scarcely then the size of a small nut, had reappeared only since the last three months. All the internal organs performed their functions freely. No other tumor existed upon the surface of the body, and the patient, who considered himself in other respects in perfect health, retained also all his natural embonpoint. I extirpated the tumor; the operation presented no difficulty, and everything went on well for about twelve days. The wound then became sanious, general symptoms made their appearance, and death took place six days after. The opening of the dead body disclosed the fact that innumerable melanotic tumors existed in the interior. The liver especially was riddled with them; they were found here in hundreds, some having the size of an ordinary pin's head, others equalling that of a small egg, and all presenting precisely the appearance of truffles, either in their crude state or reduced to pulp. A patient who for twenty years had had a melanotic tumor (grumeau) on the dorsum of the foot, without ever having experienced the slightest symptoms of general disease, desired in the month of October, 1838, to have it removed. The tumor, which was only of the size of a small nut, was readily extirpated. Seeing that the suture of the wound threatened to cause a phlegmonous erysipelas, I returned to the simple dressing and union by the second intention. Up to the present time there is no appearance of a return of the disease. But will this cure remain permanent? A woman who had undergone amputation of the great toe for a similar tumor, was not yet cured of her wound when the ganglions of the groin and iliac fossa had already become attacked to such an extent that in less than a month she had in those regions enormous black masses, which soon caused her death. However slight therefore may be the grounds for believing that there shall exist any remote engorgement or internal derangement, the surgeon should rank melanotic tumors in the category of the *noli me tangere*.

## § II.

In the case of *cerebroidal* (cérebroides) tumors, we must proceed nearly in the same way. Nevertheless, if the disease exists in a subject who is still young and in other respects in good health, and if the lymphatic ganglions situated above remain wholly unaffected, and the tumor is of recent date and perfectly well defined, the chances of cure are assuredly greater and more numerous than in the case of melanotic tumors.

## § III.

In a *scirrhus* tumor there is less tendency of reproduction in the midst of remote organs; but more frequently than the two varieties of which we have been speaking, it reappears upon the place only or

in the neighborhood of the part which the first tumor occupied. It is because this class of tumors present themselves under the form of a degenerescence or transformation of the natural tissues, as well as under that of abnormal productions and simple foreign bodies. It results from this that a scirrhus is usually badly defined, and that it often sends out to the circumference radiations or roots whose terminations cannot be traced without difficulty. Moreover, it is advisable when we have decided upon operating, to remove at the same time a sufficiently large proportion of sound parts, and we should abandon the attempt to relieve the patient, if there existed in the neighborhood of the tumor, either beneath the skin or even in the substance of the integuments, the slightest indurated plate (plaque) or smallest lardaceous radicle that could not be extirpated. In cases of melanosis and encephaloid matter, our attention is to be directed towards the condition of the remote organs; while in cases of scirrhus on the contrary, it is the vicinity of the tumor which is to be specially examined.

#### § IV.

*Colloid* tumors, which besides being sufficiently rare, often attack the bones, have this peculiarity, that they usually remain local, and well defined like cerebroidal tumors, at the same time that they seem to be concentrated on the organ which was their primary seat. It is these, consequently, in which the operation presents the most chances for success.

#### § V.

The operations proposed for cancerous tumors are the same as those for the tumors designated in the preceding articles. It is not my intention at this moment to speak either of internal remedies, or of the topical applications purely discutient or resolvent that have been so much lauded by some persons; experience having proved that such means are totally inefficient when legitimate cancerous tumors are under treatment. I would say the same of compression, if it had not found among us new advocates. For myself, I do not believe that compression has ever radically cured or dispersed tumors belonging to either of the four kinds which I have just been treating of. If it should be contended that it at least has the advantage of lessening or extinguishing the engorgement, and thickening of the neighboring tissues, (*l'empâtement du voisinage*,) and of thus rendering the other operations more easy, I would reply, that this is a specious argument which cannot sustain a close examination. In fact, cancerous tumors are not generally accompanied but with a very slight engorgement of the surrounding parts; moreover, to have any real hope of success, it is important to remove with the tumor a sufficiently large portion of sound tissue. But what would compression do in a case of this kind? Suppose it should have shrunk the tumor and diminished its volume; the instrument might be carried nearer to its confines, but we should to the same extent increase the chances of a return. Unless, therefore, inflammation or chronic engorgement of the cellular tissue should have been established around the principal disease, compression must be rejected from the *curative* treatment of cancerous affections.

A. *Cauterization*.—The destruction of cancers by means of the hot iron or chemical caustics has been eulogized at every epoch. In spite, however, of the successes obtained by means of their powders or pastes, they had been generally renounced by Rousselot, and Frère Cosme, when their efficacy has been again announced by practitioners in Germany, England and France. Arsenical caustics and nitrate acid of mercury, besides being hardly applicable except to superficial cancerous plates, have, moreover, the inconvenience of being partially susceptible of absorption, and of thus exposing to actual poisoning. The zinc paste, introduced into practice by M. Canquoin, having the property of mortifying the tissues in the manner of a punch, to such depth as is desirable, would always deserve the preference if it would adapt itself to the anfractuosités and inequalities of certain tumors, or did not exact the previous destruction of the epidermis. Whenever this paste cannot be applied with facility we may make use of the Vienna caustic or paste, which has the advantage of being introduced in the manner of a pulp into every possible chink, and of moreover cauterizing with great energy; (see Vol. I.) Potash so called, butter of antimony and the concentrated acids are, therefore, excluded from the catalogue, in consequence of their tendency of fusion into the sound tissues, and their uncertainty. But caustics, of whatever description they may be, ought they to have the preference over the operation, when the question under consideration is cancerous tumors? On this point it is necessary that we should understand ourselves; if the skin is sound and the tumor movable, and can be cut out by a bistoury so as to leave a wound whose lips may be more or less perfectly approximated, caustics will not be admissible except in those patients who absolutely refuse extirpation. If the tumor has more width than thickness, includes the integuments, is ulcerated upon its surface, is situated at the bottom of an ancient wound, and prolonged into some cavity to a great depth, and soldered (*plaquée*) as it were against the bones; if, in a word, it is not possible to remove the cancer without causing a loss of substance equal to the integuments, then caustics, and the zinc paste, especially that of Vienna, may be made trial of, and would in some cases even deserve, I think, the preference.

B. As to the *cutting instrument* and the ligature, they should be employed here according to the rules which I have pointed out under other tumors, especially for fungous sanguineous tumors. I shall, however, return to this subject in detail in treating of tumors of the breast. This last remark renders it unnecessary for me to treat of cancerous tumors according to the regions or organs they attack. I will only add that for a tumor of the foot, which extended to the bones of the tarsus, I deemed it proper to amputate the leg; that in a case of cerebroid tumor of the calf, I amputated the leg at the knee; that an enormous mass of the same nature which occupied the leg of a young sailor, induced me to give the preference to amputation of the thigh; that for a scirrhus tumor of the metacarpus, I amputated the wrist; that for a colloid mass upon the radius, I amputated the fore-arm; that analogous tumors have induced MM. Luke, Janson, Roux, Castara and others, to amputate the shoulder; that I have disarticulated the arm for a disease of the same kind; and that as a general rule

we ought to prefer amputation of the limb to extirpation of the tumor, whenever the disease penetrates to the neighborhood of the bones, so as to implicate a portion of the muscles, nerves, and large vessels. Underneath the skin, on the contrary, and in the substance of the tegumentary tissue, it is advisable to treat cancers by simple extirpation, or by caustics. A woman who had a cerebroid plate as large as the hand between the umbilicus and the epigastrium, was cured by means of two applications of the zinc paste. Another woman, who had upon the thorax, below the left shoulder, an analogous plate which was hard and without ulceration, was relieved by the following process: having raised it up a little, I glided the knife under it flatwise, and immediately detached its lower half, completing its isolation with a second cut by returning the edge of the knife from above. The wound, which did well during fifteen days, having taken on a sanious aspect, and become covered with inequalities of a bad appearance, the idea suggested itself of covering it with a layer of zinc paste. After the fall of the eschar, the wound went on rapidly to cicatrization. I have met with and destroyed plates and tumors of the same description upon the leg, thigh, around the knee, at the breech, upon the side, in front of the chest, on the side of the neck, and upon the cranium and face in an infinity of cases, but without the operative process having exacted any thing special that requires to be related here. It will also be under the head of cancerous tumors of the breast, that I shall have an opportunity of discussing the advantages and inconveniences of immediate or secondary reunion, and the different kinds of anaplasty that may be employed after the removal of cancers in general.

#### [CANCEROUS TUMORS.]

In thirty cases of *cancerous tumors of the breast* treated by M. Tanchou, (see *Journ. des Connaiss.*, &c., de Paris, Dec., 1842, p. 253,) he has obtained, he asserts, ameliorating results, and more or less complete dispersion of the tumors, by means of *graduated and methodical compression*, by compressors specially adapted to this purpose, and also by external applications of sachels containing iodate of potash, pulverized sponge, (eponge en poudre—meaning, probably, burnt sponge, a remedy of 2000 years' standing in bronchocele,) chlorhydrate of ammonia, and chlorhydrate of soda; also other compounds made with the powder of sponge, nitrate of potash, and Florentine iris. He proscribes all surgical operations.

M. Martinet de la Creuse has ingeniously proposed, and several times succeeded, (see Malgaigne's *Manuel de Méd. Operat.*, 4th edition, Paris, 1843, p. 118,) in making for the wound, after extirpating scirrhus and carcinomatous tumors, a healthy flap of sound skin borrowed by the anaplastic method from the neighborhood.

M. Ollivier, who has otherwise written so well on these tumors, proposes the daring expedient (op. cit.) of inoculating their centre with hospital gangrene!

From statistical observations obtained by M. Leroy d'Etiolles, from every department of France, (see the result of these researches communicated by him to the Academy of Sciences of Paris, February

20, 1843, in the *Journ. des Connaiss.*, &c., of Paris, Mai, 1843, pp. 214, 215,) on the subject of *Cancerous Diathesis and Degeneration*, we learn the fact that out of *two thousand seven hundred and eighty* cases, communicated from 174 practitioners in those departments, there were 1192 who were not operated upon, or who died with the disease upon them. Of these, 18 lived more than 30 years after the development of the disease, which, after reaching a certain point, remained stationary and indolent. But out of 801 operated upon, either by the knife or caustics, *four* only lived to the same length of time. Of those who lived from 20 to 30 years, we find 34 who were not operated upon, and 14 in whom an operation was performed. Of those who lived from 6 to 20 years, there were 88 who were operated upon, and 228 in whom the tumor was not extirpated. So that the balance in cancerous tumors, so far as the prolongation of life is concerned, is clearly not in favor of the operation.

So far as regards a short term of existence, the difference appears to be in favor of the operation; thus counting from the first appearance of the disease, the average prolongation of life in those not operated upon is, for men, five years, and for women, five years and six months; while in those operated upon, the average, for men, is five years and two months, and for women, six years. And in these cases, we find the average of time that expired before the operation was, three years and nine months for men, and the time after the operation, one year and five months only; while for women it is three years and six months before, and two years and six months after the operation.

To those who say that the return of the disease is too often owing to the operation for extirpation having been procrastinated, by which time was allowed for degeneration to be established, M. Leroy d'Etiolles replies, that among the numbers in this table in whom the disease was reproduced, 61 had the tumor extirpated in less than a year after the disease made its first appearance; and that 30 patients who were operated upon five years after its first development, did not have a return of the disease, and that the same result occurred in 22 others who were not operated upon until more than ten years after the first appearance of the disease.

In conclusion, M. Leroy remarks, that though it may be impossible to determine beforehand, whether a tumor will remain stationary or become cancerous, it is worthy of investigation to ascertain if the *cancerous diathesis* does not produce in the subjects in whom it exists, certain characters (as for example, a change in the condition of the fluids of the economy,) by which it may be recognized.

*Fibrous Tumors* (corps fibreux) *in general*—*Fibrous Tumors of the Breast* (corps fibreux de la mamelle.)

The justly distinguished M. Cruveilhier, in a memoir read before the Paris Academy of Medicine, on *Fibrous bodies of the Breast*, (des corps fibreux de la mamelle,) (read Jan. 9, 1844—see this memoir in the *Journal des Connaissances Medico-Chirurg.*, Paris, March 1, 1844, p. 8 to p. 93,) conceives that they have not been sufficiently studied, that they are a very frequent disease, (lesion,) and that they are constantly confounded in practice with scirrhus and indurated

cancer of these organs, and as such, subjected to extirpation. He believes that such tumors are incapable of degeneration, that they never require extirpation, that they are in some sort functional, (facultative,) that when extirpated they are never reproduced, (ne répullulent jamais,) in the proper sense of this word, but are a purely local lesion and organic production, independent of every kind of general infection of the economy, whether as a cause or effect.

Neither Boyer nor Sir Astley Cooper have mentioned this disease, nor is it more than obscurely alluded to by more modern writers.

*Fibrous Bodies in general.*—Such growths were for the first time described by Bayle as found existing in the uterus. Like Bichat, however, who considered that each tissue had its own lesions, he erroneously thought these bodies were confined to the uterus. True, the conditions in this organ are most favorable to their production and development, but they are met with in all organs where fibrous tissue is found, and are composed of two orders: 1st. As *vegetating fibrous bodies*, growing from, or implanted in, (implantés,) a membranous surface in the manner of a vegetable, like fibrous polypi of the nasal fossæ, formed at the expense of the periosteum; fibrous tumors of the dura mater; and fibrous, cartilaginous and osseous tumors, which grow from the periosteum of the bones and which may be called *osteo-chondophyte*. 2d. As *non-vegetating fibrous bodies*, (les corps fibreux non-implantés,) which grow in the interior of the organs, (au milieu des organes,) such as the fibrous bodies of the uterus, those of the breasts, ovaria and testicles.

Their *general characters*, according to the author, (M. Cruveilhier,) are: 1st. That of *situation*, always in the midst of the fibrous tissues. 2d. That of *form and size*. Their form is generally spheroidal, sometimes irregular upon the surface, sometimes mammellated, at other times deeply furrowed, (sillonnée,) giving rise then to the lobular arrangement. Their size varies from a cherry-stone, or even a millet-seed, to that of the head of an adult, or even greater, their weight being sometimes equal to 45 demi-kilogrammes. 3d. *The characters deduced from the mode of adhesion and connection of the fibrous bodies, with the tissues, in the midst of which they are developed*. Vegetal fibrous bodies (above) seem to be mere prolongations of the tissue of the organ, but all other fibrous tumors are united to the parts in which they are developed, only by means of an exceedingly loose cellular tissue, so that these bodies may be enucleated with the greatest ease by means of the finger, a blunt probe or slight traction, *without ever requiring the aid of a cutting instrument*. In this respect these bodies are, in their isolation or independence of organization, similar to *encysted tumors*, with which also they are sometimes confounded. 4th. *In their characters of texture*, fibrous bodies or tumors are of an extreme density, similar to cartilage, or to the unimpregnated uterus proper. If the fibro-cartilaginous tissues of Bichat could be sustained, fibrous bodies would come under them. These bodies are, in fact, composed of parts arranged *linearly* and belonging to the albugineous tissue, strongly pressed against each other, interlaced together in every possible direction, and often divided into many groups of fibres, and pelotoned (pelotonnées) in such manner as to constitute distinct masses or lobules. They are provided with veins whose

trunks are on the surface, and their minute branches distributed to their substance. When these tumors are lobulated, veins of greater or less size are found in the intervals of the lobes. These veins communicate directly with the proper tissue of the organ in which the tumors are. No *arterial vessel* can be traced into these tumors—injections from the neighboring arteries will not penetrate them, and no lymphatic vessel or nerve has yet been shown to exist in them. They therefore possess no other organic element than a fibrous tissue, supported (animé) by veins, and are reduced down to an obscure nutrition sustained by a feeble oscillatory movement of venous blood.

5th. *The evolution of fibrous bodies* presents the same characters at their first appearance as at their complete development, whether the tumor be only of the size of a cherry-pit, or has attained that of the fist (poing) or head. Facts have satisfactorily established, in the mind of M. Cruveilhier, the conclusion that if some of these bodies are primarily fibrous, and afterwards become cartilaginous or osseous, a number of them will present one or other of these last mentioned characters from the beginning.

6th. *The consecutive pathological characters* of fibrous bodies are: *a.* The consecutive results produced by fibrous bodies on the surrounding tissues, which consist only in the inconvenience occasioned by their weight, being in truth nothing more than parasitical foreign innocuous growths, having a peculiarly limited vitality, which causes no other change in the tissue in the midst of which they are developed than some indispensable modification of nutrition and circulation; *b.* The consecutive changes which are effected in the fibrous bodies themselves, and which are exceedingly limited. These bodies may indefinitely increase, or they may remain stationary. Many facts authorize M. Cruveilhier to believe that they are susceptible of an actual diminution of volume, or a sort of atrophy, or may become encrusted or penetrated with phosphate of lime, or the seat of an œdema, which dissolves the elements that enter into their composition and makes manifest their lobular arrangement. In this case, the tumor is often impregnated with a liquid which possesses, in appearance at least, much analogy to that of synovia.

*Fibrous bodies are incapable of cancerous degeneration.* “I believe also,” says M. Cruveilhier, “that I am sustained in saying (and this character is of the highest importance) that *there is an incompatibility between fibrous production and cancerous degeneration.*”

To ascertain if these general characters apply to certain organic productions observed in the mammæ, he invokes a great number of clinical facts, and some from pathological anatomy. Of all other secreting organs in the animal economy, the mammary gland, says M. Cruveilhier, presents the *greatest quantity of fibrous tissue*, and has besides adipose tissue, two essential elements that enter into its texture; viz., 1. A fibrous woof (charpente) or gangue; 2. Glandular granulations or grains, which latter cannot be well examined, except in women who have died during pregnancy, and especially after parturition, during any period of lactation; that except under these circumstances, mammary granulations are but very little developed, which feeble development is then in correspondence with the almost complete absence of secretion in this organ; that after the cessation of the menses, and especially in very old women, the granulations

seem to disappear entirely, leaving the fibrous woof only remaining. The mamma, therefore, possesses in a high degree, the conditions favorable to the development of fibrous bodies.

In the mammæ, the fibrous bodies or tumors appear as small spheroidal tumors, from the size of a millet-seed or cherry-pit to a pullet's egg, or larger. Their surface is sometimes uniform, or mammellated (*mamelonnée*), and their hardness is extreme, or as it were, stony (*pierreuse*). Generally sub-cutaneous, they may also be developed in the midst of the tissues of this organ; and are for the most part circumscribed, perfectly distinct from the tissue of the mammary gland, adhering to it only by a very loose tissue, apparently perfectly independent of this gland; they possess the mobility of a lymphatic ganglion, (i. e. gland,) and like that roll under the finger, from whence doubtless the name of *glands*, given to them in common parlance.

Thus are these characters precisely those that M. Cruveilhier has given of fibrous bodies in general.

The absence, hitherto, of all clinical and anatomical descriptions of fibrous bodies has caused them to be constantly confounded with other lesions of the breast, and especially with scirrhus degenerations of that organ—giving rise to the same rules of treatment, and the same prognosis as applicable to both. In respect both to fibrous bodies and to scirrhus degenerations, it has been asserted that such fibrous tumors of the breast as are commonly called glands, may exist for a long time without undergoing any perceptible growth, but that after 40, 45 and 50 years of age, they increase with great rapidity, and invading the surrounding parts, vitiate the whole animal economy, and present all the characters of an incurable cancer. Hence, as the consequence of such ideas, was that of the necessity of immediate extirpation—and that the sooner, therefore, this was done after these tumors appeared, the less the danger. This was the sole mode of treatment; not that practitioners asserted that such degeneration must always ensue, but being ignorant of any diagnostic marks between cancerous tumors and those incapable of such degeneration, “they preferred ten unnecessary extirpations to the omission of one that was absolutely essential.”

Even so little has been known of the pathological anatomy of mammary lesions, that encysted tumors themselves and œdematous indurations of these organs, are usually confounded with cancerous tumors, and often submitted like the last, to the general law of extirpation. “Such also, (says M. Cruveilhier, with great candor, while advocating, distinguished anatomist and surgeon as he is, humane doctrines so honorable to him, and so plainly deducible from the important truths he discloses to the profession,) was my rule of conduct fifteen years since. I postponed the advice to extirpate only to obtain time to prepare the patient for this operation, finding him always tranquil and resigned, when the terrible word *cancer* was pronounced.” Doubts, however, even then arose in M. Cruveilhier's mind, and especially from seeing in young girls, scarcely arrived at puberty, and in young women in rosy health, numerous cases of movable, rolling, circumscribed, indolent, and isolated tumors; and also from seeing a number of these tumors in the same breast, or simultaneously in both breasts. He asked himself the question if

such little tumors, whose discovery was so often due to chance, ought in reality to be considered a cancer in its first stage. This suggestion was strengthened by finding that many women who had refused to be operated upon, or in whom he had deferred it, went on for a great number of years under his observation, without any perceptible increase of size or degeneration in such tumors, though many such women had become pregnant, and suckled their children, and many of them had passed their critical period of life.

The fact of non-reproduction (*défaut de répullulation*) after extirpating tumors of this kind, may also be adduced as a clinical proof of the innocence of these tumors, and their totally foreign character to that of cancerous degeneration; for it is well known how common it is for true mammary cancers to grow again after their removal.

Proofs deduced from pathological anatomy, in favor of these positions, were soon obtained by M. Cruveilhier. An examination of a great number of mammary tumors extirpated for scirrhus or incipient cancer (*à l'état de crudité*) convinced him that several of them exhibited the same character of form, density, and texture, as the fibrous bodies of the uterus, and offered in no respect any of those of cancer. One important fact was established by this eminent anatomist, viz: that a number of fibrous mammary tumors, which, on examination, appeared at first to be full (*pleines*, i. e. round, uniform and smooth) were found, to be arranged after the manner of geodes (*géodes*). That is, on dividing them in two equal halves, each half could be turned inside out, upon itself, so as to form a hemispherical cavity, whose internal surface was then formed by the external surface of the tumor, and whose external surface was formed by the surface of the incision. But this now external surface was thick set (*herissée*) with globular vegetations or fibrous granulations, some of them isolated, and others that were branched after the manner of a polypus; these fibrous vegetations or globules, which were superposed on each other (*qui se modelaient les unes sur les autres*) being sometimes free, and at other times adherent to each other by means of small prolongations. These adjoining (*juxtaposés*) fibrous vegetations, knots or swellings, in the cases described, constituted a cavity without walls. In some cases, there was found in the centre of these fibrous bodies, a cavity filled by a viscous fluid, analogous in appearance to synovia.

M. Cruveilhier has had occasion to see many œdematous fibrous bodies of the breast, which had rapidly acquired a great size and were speedily extirpated, and which bodies corresponded exactly with the fibrous bodies of the uterus, their mass being penetrated by a viscous humor, similar to synovia, and their centre here and there occupied by numerous geodes, without membrane or cyst, and filled with a liquid matter. In conclusion, M. Cruveilhier remarks that he considers himself upon the strength of such facts, obtained from clinical observation and pathological anatomy, justified in adopting these propositions:—1. The mammary gland is subject to the development of an organic production known under the name of *fibrous bodies*. 2. That the fibrous bodies (or tumors) of the mamma, which constitute one of the most frequent lesions to which this organ is liable may be distinguished by certain signs from that kind of induration, which succeeds to chronic inflammation, and also from can-

cerous tumors; the tumor neither in chronic inflammation, nor in cancer, being in any manner distinct from the mammary gland itself, at the expense of which it is formed, and with which it is continuous without any line of demarcation; while the fibrous bodies are completely detached from the mammary gland and roll under the finger in the manner of a cyst or lymphatic gland (ganglion). 3. That as these fibrous bodies are incapable of cancerous degeneration, extirpation is not necessary, upon the supposition (*en tant que*) that these bodies may endanger the life of the patient, by the ulterior changes which may take place in their interior. Fibrous bodies constitute a lesion which is essentially local; their extirpation is, so to speak, contingent (facultative), and would not be requisite unless from the inconvenience caused by their weight and size. After fibrous bodies are extirpated, they never grow again, (*répullulent*) in the proper sense of this word; though new fibrous bodies may be developed in a breast which has been the seat of a previous extirpation.

At the sitting of the Paris Academy of Medicine, (January 16, 1844,) following that at which M. Cruveilhier read his memoir, an animated discussion arose among the members upon the merits of the new doctrines therein advanced. As this discussion (see *Journ. des Connaissances*, &c., Paris, March 1, 1844, p. 124, &c.,) was one of a practical bearing, maintained energetically through a number of sittings of the learned body alluded to, it will not be improper briefly to notice the leading points and views of some of the most eminent surgeons of Paris, (especially as our author, M. Velpeau's own views are also given in the debate,) to show what conclusions also their experience in the rapid progress of surgery, has led them to form, up to the present epoch of the history of our art.

M. Blandin considered *fibrous* tumors of the breast rare as compared with the ordinary tumors of that organ, and especially with its encysted tumors. He also believed fibrous tumors capable of degenerating, that it was impossible to distinguish them from cancer, and that there was no danger in extirpating them. M. Rochoux had found by the microscope scirrhous matters scattered through the interstices of these fibrous tumors. M. Gerdy did not always consider their diagnosis easy: as an example he mentioned fibro-cartilaginous lobular tumors, making a crepitus under the scalpel, &c., and having the same characters as M. Cruveilhier's tumors, and also as Sir Astley Cooper's *irritable tumors* of the breast. Though fibrous tumors may possess analogies to fibrous tissue, they differ from it. He has found three sorts of tumors: benign, malignant, and the doubtful, which may degenerate. The second exhibit a *depression* of the skin at the centre, when the tumor is compressed between the hands, and are marked by peculiar lancinating pains.

M. Velpeau admitted that there were, in fact, mammary tumors which did not degenerate, but he did not consider them in reality the same as the *fibrous* tumors of M. Cruveilhier, which latter are susceptible of this change. M. Velpeau considers this peculiarity to belong to tumors which he denominates *fibrinous* (*fibrineuses*), caused by the extravasation of the fibrine of the blood after a blow or a contusion. M. Cruveilhier, as M. Velpeau thinks, has included such tumors under his fibrous order. The microscopic characters of fibri-

nous tumors have, according to M. Velpeau, been satisfactorily ascertained by M. Mandl; in fibrinous tumors, the microscope discloses nothing but fibres and fibrilli. But the characters during life are not always recognizable, and it is rare that we meet with such tumors except in young people; in other words, we meet them more frequently in that class of persons. M. Velpeau does not believe fibrinous tumors of the breast capable of degenerating, any more than those of the uterus, at least such a result must be rare. He blamed M. Cruveilhier for not having entered more into the subject of the treatment, and for confining himself to proscribing the operation without pointing out some other therapeutic means. For his own part, considering that both fibrous and even indolent tumors, rarely present characters of a very satisfactory nature, and that they are a source of perpetual disquietude to the patients, he is of opinion that they should always be removed (*les operer*), this method having at least the advantage of giving confidence to the patient as well as physician, (*loc. cit.* p. 125.)

M. Cruveilhier expressed himself gratified with the remark of M. Velpeau, that fibrous or fibrinous tumors were not susceptible of degeneration; with which opinion also M. Moreau coincided. M. Roux (*loc. cit.*, p. 125) thought the consequences would be disastrous if the principles of M. Cruveilhier were admitted. He apprehended the latter had taken for his type of fibrous tumors of the breast those that are called fibrous bodies (*i. e.*, tumors or growths) of the uterus, two things essentially different. He denied also that one of their characters was that of being encysted, as encysted tumors must enclose a liquid, and such tumors are rarely fibrous. He admitted that many tumors did not degenerate; a prognosis to this effect was a subject of immense difficulty, and could only be made of young persons. He himself confessed, (and where was the surgeon who had not) that he had extirpated tumors as cancerous which were not so. He would not pretend to declare that fibrous tumors never degenerated, but thought they did not do so spontaneously, but might become degenerate (*i. e.*, cancerous or malignant) under certain circumstances. He opposed as dangerous, the principle (*loc. cit.*, p. 126) of M. Cruveilhier, that the operation should be conditional (*facultative*;) M. Roux thinks it better to operate even under this point of view. He notes the omission of M. Cruveilhier to give the characters of benign tumors: M. Roux says, in fact, there are none such; they may however, in rare cases, be absorbed by some spontaneous process or by means of local resolvents. The operation is rarely fatal, and its moral effect alone is a matter of great importance, seeing that the tumors do not return. M. Cruveilhier, in rebutting the ideas of M. Roux, also remarked that what were called *strumous* tumors of the breast were also confounded with the fibrous; but that such *strumous tumors* were *neuromas* and not *scrofulous*. He went so far as to say that the existence of fibrous tumors in the uterus was an *immunity against cancer in that organ*. M. Amussat denied the frequency of fibrous tumors of the breast; thus the Dypuytren museum, so rich in fibrous tumors of the uterus, is exceedingly deficient in those of the breast. He believed they would degenerate, and was in favor of operating always for such tumors, and even for a simple

lipoma (loupes). M. Bérard also took ground against the opinions of M. Cruveilhier. M. Lisfranc considered fibrous tumors of the breast exceedingly rare, as he had ascertained from having extracted an immense number of tumors of the breast. Yet such as M. Cruveilhier describes were not uncommon. He does not think them exempt from degeneration: and expressed himself diametrically hostile to the doctrines of M. Cruveilhier.

M. Castel (loc. cit., p. 164) called attention to the opinion of Bichat that the glandular tissue is as widely different as possible from the fibrous tissue. M. Cruveilhier remarked that the chief difference between him and his colleagues arose from their attaching a different meaning from him to the phrase *corps fibreux*. M. Blandin thought (loc. cit., p. 168) the therapeutic part of this question was overlooked, and stated that he considered it impossible to diagnose such tumors. He thought the idea too dominant on M. Cruveilhier's mind, that cancer was also constitutional and must return after an operation. M. Blandin maintained also, that a cancerous condition and fibrous tumors were not incompatible. These fibrous tumors of the breast are so rare that some practitioners, who have frequently removed tumors from the breast, declare they have never met with them, as MM. Laugier and Blandin. M. Blandin explained the non-degeneration of fibrous tumors of the uterus at Salpêtrière, because they were usually old women whose constitutions were dried up—not young, in whom the natural moisture and fluids of the parts favored such degeneration. He avers that fibrous tumors of the breast may become the germs of cancer; for, as M. Andral says, why should not the abnormal fibrous tissue degenerate into cancer when it is admitted that the normal does. M. Blandin alluded to the tumor removed by him from the vault of the palate and shown to the Academy, and admitted by M. Cruveilhier to be cancerous—proved so in fact, and to be both fibrous and cancerous by M. Mandl, who saw in it the cancerous globules scattered upon a groundwork (canévas) of pelotones of fibres—which proof of degeneration of fibrous tumors into cancer, is to be added to a similar one of Dupuytren in respect to those of the fibrous polypi of the nose. M. Blandin cited two other cases where this cancerous degeneration became even encephaloidal, and yet its removal was not followed by a return of the disease. If it be admitted, says he, that we cannot make a certain diagnosis of fibrous tumors of the breast, and at the same time that we deny the possibility of their degeneration, then ought we also to operate upon all indurated tumors which are not resolvable.

M. Cruveilhier maintained (loc. cit., p. 169) that the tumor from the vault of the palate mentioned by M. Blandin, was not a fibrous body become cancerous, but an instance of *fibrous cancer*, a very different thing. The various abnormal productions always preserve their peculiar characters; they do not undergo transformation, since cancer remains cancer, and tubercle continues tubercle, in the same way as fibrous bodies continue to remain fibrous. He acknowledges that *encysted cancers* are never reproduced, but unlike M. Blandin, he deems them exceedingly rare.

M. Gerdy (loc. cit. p. 212,) thought a difficulty arose in this discussion from each one dwelling upon the peculiar characters of

tumors separately, instead of viewing them in their *ensemble*, when we should discover a certain class of tumors, which may be distinguished both from scirrhus and from degenerate tumors. Thus, in considering these characters as a whole, when we find the simultaneous existence in the two breasts, or in one alone, of numerous small tumors, which are hard, elastic, indolent, rolling and clearly isolated, and the absence of cutaneous folds or depressions when the breast is pressed between the fingers, as is so accurately described by Sir Astley Cooper, we can no longer doubt that such are *fibrous tumors*. Difficult as the diagnosis sometimes is, there is this thing certain, that we should not operate when the tumors are clearly benign; in the opposite case, or if we are in doubt, we should operate. M. Dupuy considered that the only difference between scirrhus tumors that degenerated and those that did not, lay in hereditary predisposition. M. Lisfranc thought the less frequency of uterine cancer, dated from the discovery of the operation, which disclosed those ulcerations that are the most frequent source of it, and by which we are enabled to apply a radical cure in season. M. Amussat mentioned a case of cancerous tumor of the breast, which he had just removed, and which, in the beginning, had presented all the characters assigned by M. Cruveilhier to fibrous tumors. He contests the opinion of this surgeon and that of M. Gerdy, that it is possible to establish a differential diagnosis between indurated (*dures*) tumors of the breast. The true plan, he contends, is to operate at an epoch as little distant as possible from the commencement of the disease, which is then in most of the cases circumscribed and susceptible of being totally eradicated.

M. Roux (*loc. cit.* pp. 212, 213.) persisted in maintaining the difficulty of diagnosing the benign tumors of the breast, and urged with all his zeal the necessity of operating on tumors of the breast in good season; at the same time repudiating with equal energy, the opinion of M. Hervez de Chegoin, that we should defer operating for cancer to as late a period as possible. Here this interesting discussion closed. (Sitting of the Academy, March 26, 1844—*Journal des Connaissances*, &c., Paris, May 1, 1844, p. 213.)

The animated discussion which has taken place at Paris on *fibrous tumors* in general, and especially those of the *breast*, and the difficulty of establishing their true character and diagnosing them from cancerous and other tumors, has not ceased, but promises to incite to still farther and most important investigations. The researches, in fact, made with the *microscope*, bid fair to give a still greater value to that instrument than it acquired even in the time of *Lewenhoeck*, or than has been accorded to it for years past, which is not surprising, when we consider the mechanical improvements which art has effected in that powerful means of interrogating the internal structure of every kind of organization. (See our note on a certain fungous growth of the testicle, *infra*.)

M. H. Lebert, of Paris, has communicated to the public (*Gaz. Méd. de Paris*, March 8, 1845, tome XIII., p. 156 et seq.) some observations upon the results obtained by him in examining a tumor of the breast, which appear to us to possess a good deal of importance. The case which M. Lebert furnishes in illustration, was that of a

woman perfectly healthy in every respect, aged 32, in whom a tumor of the right breast had existed for ten years, but only latterly became exceedingly painful and enlarged, appearing to be a general hypertrophy of the gland, without adhesion of the teguments, or any feeling of isolated tumors in it, but somewhat painful on pressure. The pain caused by it warranted its removal by the surgeon, M. Lenoir. The microscope proved it to be a *hypertrophied portion of the mammary gland*, its general color white, and consisting of numerous globules, and these having throughout their interior smaller cellular globules, filled with a reddish fluid, which oozed out whenever the knife was applied. It had none of the characters of fibro-plastic, nor of cancerous tumors of the breast. The surrounding cellular tissue, by the long continuance of the disease, had also become so hypertrophied and thickened as to give it the appearance of a cyst. A *diagnostic point* elucidated by the microscope, and which went to show that this tumor was nothing more than *hypertrophied mammary tissue*, was the fact that it contained throughout *numerous large-sized nerves*, which afforded an explanation also of the acute pains, (not, therefore, to be confounded always with cancerous disease,) and proved its true character, for no accidental tissues of new growth contain these or other evidences of high organization. These results, moreover, confirm, as is remarked by M. A. Bérard in his recent work on tumors of the breast, the accurate knowledge which Sir Astley Cooper had of this kind of tumors. Those called *cysto-sarcoma*, as well as *fibrous* and *hydatid* tumors of the breast, all belong, M. Lebert thinks, to this species. The process of the formation of those under consideration he thinks is as follows: a portion of the mammary gland or of many of its lobes become the seat of a sanguineous afflux or local congestion, whence a more active nutrition and hypertrophy, both of this diseased gland and the surrounding normal cellulo-fibrous tissue. These lobes, as Sir A. Cooper says, become more prominent outwardly, and finally, are attached to the gland only by a mere pedicle, so as to appear sometimes quite distinctly separate from it. The *natural fibro-cellular* tissue which surrounds the mammary gland, becoming dense and hypertrophied more rapidly than the gland itself, is mistaken for a *fibrous* tumor, and when filled with an abundance of fibro-plastic, or gelatinous liquid, may have a *colloidal* (colloide) appearance. Or when this plastic fluid is deposited in the interstices of the fibrous tissue, it may form compartments (loges) which are ultimately transformed into small cysts, the globules of which may be considerably altered by imbibition. When these cysts exist in great numbers in the middle of the tumor, they take on the form of *mammary-hydatid*, which, however, must not be confounded with *serous-hydatid* tumors of the breast, or those which contain *ecchynocoques*, and which are sometimes found in the breast.

M. Lebert says, moreover, that those under consideration may acquire considerable volume; that they are more especially developed in young women; that they do not alter the general health; and especially do not contract adhesions with the skin which surrounds them, and that they leave the nipple (mamelon) intact: in all of which particulars it will be perceived his views differ in many points from those of M. Cruveilhier.

M. Mandl, (loc. cit., *Gaz. Méd.*, p. 157, 158,) the celebrated micrographist of Paris, who also examined the tumor in question with M. Lebert, accords with him in the existence of mammary tissue in the portions submitted by them to the microscope. Nevertheless, positive as M. Lebert's opinions appear to be on its non-cancerous character, M. Mandl asserts that he satisfied himself that *cancerous globules* were also present. He states the important fact that we must not be deceived by the *usual microscopic form* which the elementary globules of cancerous tumors are known to have; for this is sometimes not present, and he then has been enabled by other physical characters, or by chemical or other means, (which he will in due time make public,) to establish the fact that such tumors were nevertheless of genuine cancerous structure. So of *encephaloidal* (so called) tumors of the retina, though sometimes destitute of globules of the cancerous form, he has notwithstanding found them to be unquestionably cancerous.

Mr. Liston speaks of what he calls *fibrous tumors of the mamma*, (*Lond. Lancet*, Dec. 7, 1844, p. 308, &c.) which form in the cellular tissue between the mammæ, the latter becoming expanded and flattened out in front of the tumor.

But neither these nor Sir A. Cooper's *hydatid or cysted* tumors, the cells of which latter Mr. Liston has seen sometimes filled with a fluid as black as *printer's ink*, are as frequent he thinks as *carcinomatous malignant* disease of the mamma. These may occur, but rarely, in women under thirty in perfect health, with uninterrupted catamenia. Most generally they occur between the ages of forty and fifty, and sometimes later. They commence between the nipple and axilla, and sometimes in the centre of the gland, and then attack the middle of the lactiferous tubes. Sometimes the tumor remains hard and stony, with the nipple retracted, skin puckered, &c.; but usually it makes rapid progress in size, becomes soft and pulpy, or pultaceous and medullary, and throws out a fungus which may or may not bleed profusely, depending on the constitution. A section of one of these tumors, says Mr. Liston, presents a variety of diseased structure: it may be *fibrous-looking*, that is, with *white* bands running to the cellular tissue; or present the appearance of a gelatinous cancer, or it may be pultaceous or medullary. Sometimes all these heterogeneous or heterologous tissues are found in the same tumor; or some portions are hard and others softened down; or the vessels will give way and extravasation of blood occur.

In mere hypertrophy of the gland, support given to it with moderate compression may restore it to its normal size. Dr. N. Arnott's mode of pressure Mr. Liston thinks is very ingenious, i. e. by a sort of wooden cup or bowl, made of the size of the tumor, and into which apparatus is placed a small air-cushion, made of very fine texture. The cushion is inflated with air, so far as not to be hard; this cushion is then put in the cup and supported by a spring like that of a common truss. This will answer also, Mr. Liston says, in many cases of simple tumor of the breast.

There are, he considers, some enlargements of the mamma where the structure is altered; not a simple hypertrophy,—but where there

are masses of fibrine agglutinated together, and where the tumor will go on increasing in spite of all that can be done.

Cystic tumors cannot be dispersed by simple compression. Sir B. Brodie has described certain tumors of the breast that have yielded to lotions of spirits of camphor with liquor plumbi kept on till the surface is inflamed, then omitted and reapplied.

The knife only, says Mr. Liston, can remove the disease when the gland is altered in structure and contains a great number of cysts; but such tumors are not as he conceives malignant, and if the whole mass is extirpated there is every chance that the disease will not return. There is no contamination of the lymphatics, and the removal of the breast in those cases, may be had recourse to with great propriety.

If a patient comes, says Mr. Liston, with a small tubercle in the breast, with some puckering and adhesion to the integument, if it feels exceedingly hard and unyielding, and has all the characters of carcinoma, but is of recent origin, and you cannot trace disease to the lymphatic system, you may be sometimes justified in taking the tumor out, but *you must take the whole of the mamma with it*. When the disease is at all advanced, and there is reason to think that the constitution is affected with it, it is far better to abstain from the proceeding. At one time, adds Mr. Liston, this was the most common operation in surgery. I recollect the period when a week seldom passed over without the operation being performed two or three times in our hospitals; but now it is seldom had recourse to, and properly too, except in cases of *non-malignant* disease.

Mr. Liston has seen a case of carcinomatous tumor of the breast in a female under 30, (see his *Lectures, London Lancet*, Dec. 21, 1844, p. 359, &c.) where the skin covering both sides of the chest and all around the back was affected, hard, unyielding and extensively pervaded by tubercles, to such extent that the motions of the chest and of the upper extremities were much impeded by the indurated state of the skin.

Cancers of the mamma may at an early period be disposed to involve the lymphatics, the same as in those of the lip. Even in malignant disease, Mr. Liston has known Dr. Arnott's mode of compression, if early and well applied, to cause the tumor in great part to disappear: but in other cases it causes great suffering; for it cannot be expected to liberate the system of the constitutional taint, which will then reappear in the neighboring lymphatics and at places far removed from the disease. Thus, though the fatty matter around the mamma has been absorbed by the pressure, and the tumor lies flat on the ribs, yet the disease goes on as if nothing had been done. Dissection in such cases has shown enough cancerous degeneration.

In *cystic and fibrous* tumors however, he thinks the operation may be undertaken with a very fair prospect of success; but sometimes the disease returns, and is sure to do so if the whole of the tumor is not taken away.

*Pseudo-Cancers*.—You meet sometimes with tumors, says Mr. Liston, (*Ibid.*, p. 359, 360, &c.) which are not *described in books*, and which you will scarcely believe malignant, or that they can possibly

return. He describes one of this kind in a stout healthy woman, only a little over 30, and in whom the lymphatics were not in the slightest degree affected. There was found a great deal of fatty matter around it, and its interior to his surprise consisted of a strange soft-looking mass, containing a great deal of *coagulated blood* and a quantity of clot without the coloring matter, but there was also curious pultaceous stuff amongst it. After this he was not surprised to find that the disease in a few months returned, showing itself in three or four fungous buds in the cicatrix. There being still no affection of the lymphatics nor of the axillary gland, Mr. Liston removed these, and with them, as the patient was so stout, an immense quantity of the surrounding tissue, skin, fat and even pectoral muscle, for the tumor adhered firmly to the fascia of this last and was incorporated with its fibres. The cure was complete, and remains so now, nine years since the last operation.

In *non-malignant* tumors, Mr. Liston has sometimes cut below the mamma and left that behind, but if there is adhesion to it the whole must be sacrificed.

In *malignant tumors* when extirpated, not only the diseased mass must come out, but you must be careful, he says, to cut out also a large portion of the apparently healthy fatty tissue around it, and keep the knife also much beyond and outside of the *white bands* which you will see spreading out from the central portion of the tumor into the fatty matter. After taking out the tumor, it is to be washed and scraped, and if any indurated portions be found on its surface, you must proceed to make further excisions from the corresponding parts of the wound.

It is a good rule, he thinks, to take away *the fascia of the pectoral muscle*; as the disease frequently has some connexion with it, and will recommence in this tissue.

Mr. Liston thinks it an advantage in the dressing to apply a layer of *gold beaters' skin* to the raw surface of the wound, to prevent this adhering to the lint, which is to be placed upon this intervening tissue.

Again, Mr. Liston disapproves of closing the edges of the wound tight at first with adhesive plaster, and by making firm pressure with compresses and rollers around the chest; as this causes pain and oozing of the blood, and the formation of putrid clots, fœtid discharges, &c., requiring the whole to be removed, and perhaps more vessels to be tied. He prefers merely the lint applied as mentioned above, wet for five or six hours, then one or two sutures, or more, may be required, and to terminate by bringing the edges together with *isinglass plaster*. Thus you will probably obtain union by first intention, and without discharge or pain.

The *male breast* occasionally will become affected precisely, he says, in the same way as the female, and require also removal, or it will end in internal malignant disease and death.

M. Lesauvage of Caen, (*Arch. Gén.*, Février, 1844, p. 178, &c.) disapproves of the word *fibrous*, and proposes, in lieu thereof, *gelatino-fibrous*, to such tumors as are described by our author, M. Velpeau, (*Dict. de Méd.*) as formed of *solidified or vitalized* (vivifiée) *fibrine or albumine*. M. Lesauvage says they are to be found in those regions that are abundantly supplied with cellular tissue, and that he

has seen them in the breast, scrotum, fold of the groin, posterior part of the thigh, mesentery, &c. They are always isolated, and possess a distinct organization within themselves of numerous cysts and blood-vessels, and incommode the neighboring parts only by their size, weight and pressure. In the breast they are always developed at the posterior part of the gland, which latter, when they are very large, is flattened out and covered by them on its anterior portion. M. Lesauvage does not describe these tumors, which he has seen return after extirpation, in *seven* instances, with sufficient clearness to enable us to appreciate probably at their just value the fruits of his experience. A discussion which has elicited such profound researches, microscopic, pathological and otherwise, from the most learned surgeons and investigators of Paris, cannot properly be participated in by others, unless they come duly armed with accurate and new facts.

M. S. Tanchou in a more recent work of his, (*Recherches sur le traitement médical des tumeurs cancéreuses du sein*, Paris, 1844,) boldly reassumes the prevailing popular doctrine of *conservativeism* and the substitution of *medical* treatment even in that most formidable of all surgical diseases, cancer. He maintains that by a proper medication the most clearly established and unequivocal forms of cancerous tumors of the breast, may be effectually arrested in the economy, and in their local devastation. He strongly censures the frequent resort to extirpation, where not necessary, and for alleged cancerous tumors that are not in reality cancerous. From a comparative table of deaths by cancer, at Paris and its environs, between 1830 and 1840, but from which no doubt there must be a great deduction made for errors in the true designation of this disease, as is justly remarked by the editors of the *Archives Générales*, (4<sup>e</sup> serie, t. VII., April, 1845, p. 523,) M. Tanchou asserts that this disease has increased in frequency from 1.96 in a 100 in 1830, to 2.40 in a 100 in 1840. But according to a more important table by Professor Rigoni Stern of Padua, (*Arch. Gén.*, loc. cit., p. 524,) embracing an interval of 80 years, viz., from 1760 to 1839, the same increase of mortality from cancer has taken place at the last mentioned city; viz., from 48 in 1000 between 1760 and 1769, it rose to 93 in a 1000 from 1830 to 1839; but this increase was exclusively confined to cancers of *the uterus*. Whereas, M. Tanchou states the augmentation in Paris to have taken place in all the most important organs and in proportion respectively to their greater degree of excitability or impressionability, and this in their physiological order. He however also admits that the increase has occurred to a greater extent in women. M. Tanchou imputes this increase of the disease to the effects of civilization, and in support of this, instances the less degree of frequency of deaths by cancer in the environs of Paris than in the capital itself: an error in the tables which, as is again justly remarked by the editors of the *Archives Générales*, (ib. loc. cit., p. 524,) is to be ascribed to the fact that the poorer class of patients in the suburbs most usually come for relief to the hospitals within the city proper.

*Fungus Hæmatodes occupying the entire bladder.*—Dr. E. Bissell, of Norwalk, Connecticut, (*American Journ. of the Med. Sciences*, new series, vol. VII., p. 122–124, Philad. 1844,) relates one

of the most extraordinary cases of isolated and sudden formation of malignant disease of the bleeding fungoid description on record. In the short space of one year, a man aged 67, who was of temperate habits and up to April, 1842, had enjoyed uninterrupted health and a sound constitution, was seized with irritation in the bladder and constant desire to urinate, followed by discharge of large quantities of blood, and distressing pain and exhaustion, which finally ended in death. The surgeon, previous to this event, diagnosed through the rectum and above the pubis, an enormous tumor occupying the whole bladder, and thus dispelled the illusion of gravel and stone, for which supposed diseases he had been for some time under treatment by an empiric. On examining the body, the diagnosis was fully confirmed. The tumor was ovate, and nine inches from above downwards, and about four and a half inches transversely. Its greatest diameter was naturally towards the abdomen and perineum, from meeting with less resistance in those directions. It was a true fungus hæmatodes, and originated near the neck of the bladder posteriorly. Its texture could be torn by the finger without much difficulty. The bladder was so completely filled up by it that there was not room for the smallest quantity of urine. The most remarkable feature is, that there was not a vestige of disease in the kidneys or other viscera any where!

A congenital *encephaloidal* tumor, or *encephalocele*, of an extraordinary character, proving on dissection to be a true *hernia cerebri*, has been recently described by Mr. W. Lyon of Glasgow, (*Lon. and Edin. Month. Journ. of Med. Science*, by J. R. Cormack, M. D., &c., Nov., 1844, p. 983; and the *London Medical Gazette*, July 12, 1844.) The child, aged nearly one month, at the time of the description of the case, exhibited an oblong tumor, chiefly over the occiput, and extending from the vertex to the nape, 11 inches in circumference, 9 in length, and 7 in its lateral dimensions, partially livid or marbled in color, fluctuating and *without pulsation*; traversed anteriorly by small tortuous vessels, and the parts not livid covered with thin soft hairs. No opening could be felt under its attachment to the scalp—the head was normal, but the forehead remarkably low, and receding—the child well formed, but weakly. The tumor being without pulsation and nearly as large as the head, and the cranium of normal size, were circumstances that *masked* its true character and led to the inference that it could not be connected with the brain or composed of cerebral matter. This opinion was strengthened by the fact that the fontanelles remained flaccid and could not be made tense by pressing on the tumor, as if to effect its retrocession by a hernial taxis. Gentle compression was tried, but soon abandoned. Finally, the edge of an opening into the cranium could be felt. The child lived just a month, and the tumor, on dissection, was found to contain 3 oz. of bloody serum, and its parietes to be formed of the scalp, pericranium and dura mater. Portions of the posterior lobes of the cerebrum, about the size of a small apple, covered by the arachnoid and pia mater, having a film of serum between them and the dura mater, projected through an opening in the inferior and middle part of the occipital bone into the sac, being of the size of the point of a finger, with rounded edges, and situated immediately above the *tentorium*, which was imperfect. It was bounded above by the termi

nation of the longitudinal sinus, at the sides by the lateral sinuses, and below by the incomplete tentorium. The portion of brain in the tumor was compressed where it passed through this abnormal foramen, and bulged out to the size of a small apple in the interior of the sac. There was no fluid within the cranium, either beneath the membranes or in the ventricles. The substance of the brain was quite normal. The impacted state of the parts about the occipital opening, no doubt prevented pulsation from being felt externally.

Cases of this description, though possibly beyond the reach of surgical aid, are rendered exceedingly valuable by the difficulties and delusions with which a post-mortem may show the diagnosis to have been necessarily embarrassed.

Even the *brain* itself is not exempt from the formation of *scirrhus tumors* within its substance. A remarkable case of this kind is related by M. Frestel, (*Gaz. Méd.*, de Paris, April 19, 1845, p. 253,) of an infantry soldier of young and robust constitution, who was received into the hospital of Saint-Lô, and who, after months of acute suffering from pain in the occipital region, but what is unaccountable, without, so to speak, any fever, or the least deviation of any of the mental or physical functions from their normal state, except perhaps a slight defect at times in the articulation of words, ultimately died suddenly without convulsions. The organs of the different cavities and the cerebrum itself was also found normal, except that there was a considerable quantity of serosity in its ventricles; but on examining the *cerebellum*, its entire left portion was found disorganized, increased in volume, and having small but well-marked mammillary eminences on its superior surface. The inferior and posterior part contained a tumor of the size of a large nut, supported on a distinct pedicle. The right portion of the *cerebellum* was in a measure healthy. The tumor was hard and resisting to the touch, and of a tallowy (*lardacé*) aspect, and when cut into exhibited the characters ascribed by authors to scirrhus tissue. T.]

## CHAPTER XI.

### TUMORS OF THE BONES (EXOSTOSES).

Under the title of tumors of the *bones*, my intention here is to speak only of the class of tumors designated by the name of exostosis. Surgical remedies are not applicable to all the varieties of exostosis. So long as the malady is still the seat of an inflammatory process, and that it presents the slightest character of osteitis, acute or sub-acute, there would be danger in attacking it with instruments, and the operation would be absolutely without any result. It is its cause that we must extinguish, and not the exostosis, which we have to treat. In the acute state or in a state purely chronic, exostoses, developed under the influence of syphilis, or any other general infection, are equally repugnant to every kind of surgical operation, so long as the

germ has not been completely destroyed in the system. Should the exostosis be complicated with caries, necrosis, tubercular, sarcomatous or other degenerescence, it is still to these last affections that we must address ourselves, and not to the exostosis, properly so called. Finally, operative surgery ought moreover to exclude from its domain diffused, large or fusiform exostoses, and those which comprise the whole circumference of cylindrical bones, or the entire thickness of the large bones to a great extent. I will add, that limited exostosis, more or less completely pediculated, ancient and indolent, which is almost the only kind that ought to be attacked, would not of itself justify serious operations, unless by its situation or volume, it should in reality cause a great disturbance in the exercise of some of the functions, or unless it should trouble in too serious a manner the regularity of the features and forms of the part. Exostoses being very common, have naturally very early attracted the attention of surgeons. Heliodorus (Peyrilhe, *Hist. de la Chir.*, p. 391, 392,) who seems to have been acquainted with eburnoid exostosis (l'exostose éburnée), positively recommends their removal. The ancient Greeks, who often employed the hot iron in place of the cutting instrument in such cases, also made use of both these means at the same time. J. L. Petit (*Œuvres Posthumes*, t. II., p. 27,) who adopted the same method, adds that exostoses which have not been dissolved neither by mercury or other internal remedies, ought to be destroyed by means of the exfoliating trephine, chisel and mallet, (*Maladies des Os.*) About the same epoch Duverney (*Maladies des Os*, t. II., p. 500,) a rival of J. L. Petit, laid down the following principles: if the exostosis has not a large base, it is to be removed, he says, by means of the rasp, chisel or saw; when the exostosis, on the contrary, is large, we ought to give the preference to the exfoliating or ordinary trephine, taking care to place the crowns by the side of each other, in order afterwards to drive out and to remove by means of the strokes of the chisel the bridges that remain between them. The red hot iron and caustics found, at the beginning of the 18th century, a decided antagonist in Kulm (*De Exostosi*, etc., 1732; *Thèse de Haller*, t. V., p. 653.) Extirpation with the knife, says the author, is the only remedy for exostoses, all other means being doubtful and uncertain. Lecat, wishing to reconcile the various ancient modes of practice, recommended in 1755, under the anonym of Labissière, (*Prix de l'Acad. de Chir.*, t. VII., p. 157, in-12,) the excision of exostoses which have a tendency to imposthume or which are limited to the interruption of certain functions; the hot iron against those which are complicated with fungosities and deep-seated caries; delay for those which no longer make any progress and which do not cause any accident. This doctrine did not prevent Allan (*De Exostosi*, § 12; *Thèse*, 1770) from proposing the removal of exostoses in two stages. Having incised the integuments, scraped the periosteum, and dressed the wound dry, Allan recommends that we should, on the following day, apply a sufficient number of the crowns of the trephine; that we should then, by means of the gouge and mallet, drive out the osseous bridges, and terminate by rasping the bone which sustained the exostosis. It is readily conceived that this method could neither be

agreeable to the taste of the patient or the surgeon, and that Nicolas (*Dict. de Chir. et de Méd. et de Vétér.*, t. I., p. 521, 522,) who simply recommended to saw through the base of the exostosis, when it is narrow, found more sympathy among practitioners. Since then an attempt has been made to systematize these different modes.

B. Bell (*Cours de Chir.*, t. V., p. 314,) and Maune (*Maladies des Os*, p. 19–33–35) after him, have established, that an exostosis ought to be attacked with the trephine, if it can be included in the crown of the instrument, and with the ordinary saw when it is too large—When the exostosis surrounds the whole circumference of the bone, we must, say these authors, exsect or amputate the part, whether it exists in the small bones of the feet and hands, or even when it is situated in the thigh, leg, or arm. Petit-Radel (*Encyclop. Method.*, partie Chirurgicale) in such cases also recommends to exsect the cylinder of the bone, rather than confine ourselves to the excision of the exostosis. Surgeons, nevertheless, have pursued a more simple practice. With Voigt (Plouquet, *Suppl.*, p. 53, col. 3,) the extirpation of an exostosis succeeded very well and enabled him to preserve the continuity of the part. M. A. Cooper (*Œuvres Chirurg.*, translation of Bertrand, t. I., p. 306) recommends removing them with a saw, and says that the operation, which under such circumstances is accompanied only with a slight pain, does not in general involve any danger when it has been well done.

The ligature mentioned by Klein (Sprengel, *Hist. de la Méd.*, t. VIII., p. 341,) does not in reality deserve a refutation, since it appears so entirely foreign to the treatment of exostoses. In conclusion, it is not, in fact, allowable to undertake the removal of these tumors, unless it should appear practicable to reduce them by means of the saw, or to destroy them by the chisel or the trephine. By means of the cultellaire saws, the chain and rowel saws, and the improved osteotomes, which science possesses at the present time, there is scarcely an exostosis, with a strangulated or pediculated base, which cannot be readily extirpated. The operative process being simple or complicated, much less from the nature or form of the exostosis, than from the anatomical arrangement of the organs which surround or sustain it, cannot be well understood except when treating of exostoses in particular. It is, moreover, evident that certain of these tumors, those especially which are superficial and perfectly pediculated, are generally easily removed. An empiric (Guérin, *Essai de Méd.*, t. II., p. 276, an VI.) supposing that he was about to lay bare a lipoma, having perceived his error and recognizing before him an enormous exostosis, isolated it down to the level of the sound bone, and succeeded in detaching it by means of a common carpenter's saw: the patient got well.

## ARTICLE I.—EXOSTOSES OF THE TRUNK.

### § I.

On the *cranium*, the extirpation of exostoses has not always been unattended with inconveniences; it is moreover easily performed. Having laid bare their root by means of suitable incisions, nothing

prevents our dividing them either by the ordinary saw, the hand-saw, or the trephine. Nevertheless, I would recommend that on this part of the body we should not have recourse to the gouge and mallet, unless it were necessary, and that in order to avoid all cerebral concussion, we should confine ourselves to the employment of the different kinds of saws which I have just spoken of. Arnaud, (*Mercur de France*, Janvier, 1716,) speaks of an exostosis four inches long and two in breadth, which was situated on the top of the head of a domestic, and which was first attacked with a trephine. Perceiving that the tumor was osseous throughout its whole substance, the surgeons deferred the operation until the next day. Serious accidents which came on in the night, obliged further postponement, and the patient succumbed at the expiration of three days, without the autopsy throwing any light on the cause of so sudden a death. We also find in Sauvages (*Nosologie*, t. VI., p. 235,) the history of a patient who had in the auditory passage a tumor that was taken for a foreign body, but proved an exostosis, which was attempted to be extracted, but soon caused death. M. A. Cooper, (*Œuvr.*, trans. of Bertrand, t. I., p. 310,) cites a case of fungous exostosis of considerable size, which occupied the two tables of the frontal bone, and which was excised, but in such a manner that the person operated upon died on the sixth day. We must not, therefore, undertake the ablation of exostoses of the cranium without necessity, nor resort to this grave remedy unless the tumor has excoriated and ulcerated the tissues, and that it is entirely external or threatened with some degenerescence.

## § II.

The *bones of the face* have still more, perhaps, than the bones of the cranium been the seat of exostoses, and for which serious operations have been fearlessly undertaken. It is to be remarked, in fact, that in this region surgeons have obtained numerous successful results. Brutner (Koenigsberg, 1775, observ. premiere) speaks of a patient who, in consequence of a fall when six years of age, had on the jaw an exostosis which was extirpated eleven years afterwards, and which then weighed six ounces. Reisinger, (*Bull. de Férussac*, t. XI., p. 361,) states that he successfully removed from the upper jaw, an exostosis of certain volume by means of Thæter's saw, when all other processes had failed. Should the exostosis occupy the lower jaw, it must be destroyed in the same manner. Jourdain, (*Maladies de la Bouche*, t. II., p. 123,) in order to remove one which was situated on the outside of the jaw, incised and dissected the gum around it, to detach it by means of a flat slightly curved chisel with a sharp edge. The actual cautery was afterwards found necessary, to destroy a purulent exudation from the traumatic surface, and the patient recovered in 34 days. This method, recommended by Blicke, has been favorably received by M. A. Cooper, who, in a case analogous to that of Jourdain, detached the exostosis by means of the bistoury, and afterwards deemed it necessary to apply the cautery to the bottom of the wound. Other cases of exostoses of the jaws destroyed by the instrument or by the hot iron, have also been reported by Harrison,

(Sprengel, t. VIII., p. 366, 1832,) Mosque, (*Ancien Journ. de Méd.*, t. LXXI., p. 506,) and Verduin, (*Thèses de Haller*, t. V., p. 69.) One of the most curious examples of exostosis of the face, successfully removed, is that related by Vigarous (*Opuscles sur la régénération des Os*, p. 170.) The tumor occupied the vault of the palate, and extended from the neighborhood of the anterior palatine foramen, as far nearly as the uvula. Its largest diameter was ten lines. The surgeon having assured himself that it was only soldered as it were against the bones, attempted to detach it without penetrating into the nasal fossæ. There remained around the cavity where it was situated an osseous border, which afterwards came away in fragments, and did not prevent the cure from being accomplished in the space of a month. Should the exostosis be situated in the vicinity of one of the alveolar borders, the cutting pliers, which I mentioned under the article of *exsection of the jaws*, would render its excision one of the easiest things imaginable; Liston's scissors would be equally applicable to it, should it be dilated, while presenting at the same time a root that was slender and of sufficient length. Wounds of the face, moreover, reunite with so much facility that incisions should not be spared in this region, should it appear that they would render the destruction of the exostosis more easy and more certain.

### § III.

In exostosis of the *sternum*, I have met with but one instance in which its form and character would admit of extirpation. The tumor was of the size of a pullet's egg, and its root one-half less in diameter than in its dilated portion. It was laid bare by two curved incisions, which detached an ellipse of the skin in front; its section was afterwards made by means of two cuts of the crested saw, directed first from right to left, then from left to right, and as near as possible to the anterior plane of the bone. The borders of the wound were then gently brought together and the operation was unattended with any serious consequences.

### § IV.

I have also, in two instances, met with exostoses on the apex of the *spinous processes* of the vertebral column, and which I might have extirpated, in one case, on a level with the projecting vertebra, and in the other, in the lumbar region. But nothing was done to remedy this deformity.

### § V.

The *bones of the pelvis* sufficiently often present these kinds of exostoses. A patient had one of very large size on the pubes, which caused him a good deal of suffering. M. A. Cooper (*Œuvr.*, transl. of Bertrand, t. I., p. 320,) effected its removal, using Machel's saw to begin with, and finishing with that of Hey. The cure was completed in a month. I have met with a young man who had on the outside of the spine of the ilium, on the left side, an exostosis a half an inch in thickness, half a foot long, and near twenty lines in breadth, which was situated transversely, and caused, moreover, no

pain, and had, according to the patient, been developed in less than two years. The young man was not willing to submit to any operation for his relief. I have met with exostoses in the same situation in three other persons; but in these cases they were of such considerable size that I have not thought it necessary to recur to surgical means. Exostoses in the interior of the pelvis, are among the most frequent that we meet with, the proof of which I have given elsewhere, (*Traité d'accouchements, Vices de conformation, Accouchements contre nature*, etc., 2d edition;) but as they are beyond the reach of operative surgery, it is useless at this time to examine them.

Plessman, who asserts that he destroyed one on the anterior surface of the sacrum, by means of the actual cautery, has not been relied upon by any one, and has left it to be inferred, that the tumor he refers to, was one of an altogether different description.

## ARTICLE II.—THE HAND.

### § I.—*Hand.*

In the limbs especially, exostoses require all the attention of the surgeon. Covillard (*Obs. iatro Chirurg.*, p. 97, obs. 36, 1739,) extirpated one under the name of a wen, (*loupe*), of a cellular texture, of the size of a pullet's egg, and transparent as a crystal, and which extended from the phalangeal articulation of the little finger to the middle of the hand. The incision of the soft parts having been effected, Covillard made use of a shoemaker's knife to complete the operation, and his patient recovered. An exostosis of considerable size, which was situated upon the same finger, and which incommoded only by its size, was also at a later period successfully removed by Bidloo (*Exercit. Anat. Chir.* 9, *De Exostosis*.) It must be that these exostoses of the little finger are quite common, for M. Champion, also, gives two examples of them: in the first case (communicated by the author) a bosselated transparent tumor, of the size of a goose's egg, was situated upon the inner side of the first phalanx of this finger. Having operated in the manner I have described in speaking of exostosis of the sternum, the surgeon made use of a solid scalpel to force out (*faire sauter*) the exostosis, and afterwards had recourse to the gouge, to remove everything from the phalanx, that had the appearance of being expanded (*raréfié*), fungous (*carnifié*), or diseased. In the second case (*Thèse* No. 11, Paris, 1815, p. 61; obs. 10) the tumor was situated upon the outer side of the forefinger, towards the middle of the first phalanx. It was of the size of a nut, and other practitioners had proposed to destroy it by amputating the finger. An osseous tumor of three inches and a half circumference, developed itself upon the second phalanx of the forefinger; Vigarous (*Œuvr. Chir.*, p. 458,) made an incision, which included the entire base of the exostosis, and enabled him to detach it in two successive stages, by means of a fine saw, by removing half the corresponding metacarpal bone, and then the forefinger itself. The same practitioner, also, had to remove from the outer side of the right middle finger, what he called an osseous *loupe*, and which kept the two fingers six inches apart. This tumor, which was seven or eight times

larger than the bone which sustained it, and which formed a kind of shell to it, was filled with matter resembling tallow or honey. Vigarous (*Opusc. sur la Régén., &c., p. 172,*) removed the first phalanx of the diseased finger, together with the second bone of the metacarpus, and cured his patient in the space of six weeks. M. A. Cooper, also, speaks of an exostosis which occupied the second phalanx of one of the fingers. The first ablation was followed by a return, but the second effected a radical cure. In another case, Vigarous encountered an osseous *loupe*\* on the first bone of the metacarpus. This tumor, which was thirteen inches and a half in circumference, at its dilated portion, and nine inches at its root, appeared to have been developed at the expense of the second and third bones of the metacarpus, as well as of the first.

## § II.

I have seen exostoses on the *fore-arm*, which were in some instances globular, and at other times *styloidal*. But the patients experienced so little inconvenience from them, that they never thought of having them removed.

## § III.

The *humerus* occasionally presents on its outer side and near the shoulder, an osseous tumor, the extirpation of which has already been several times attempted. The first example of the kind which has been spoken of among us, belongs to Ant. Dubois. I have heard this surgeon relate that the exostosis, which was concealed underneath the deltoid muscle, was situated nearly two inches below the articulation; that it was of the size of a large pullet's egg, and that it became necessary to cut through the muscular fibres, in order to lay it bare, after which he made use of the ordinary saw, gouge and mallet to complete its extirpation. In another case which I have seen, the tumor was situated precisely in the same region, and presented nearly the same volume. M. Roux, who performed the operation, being desirous of saving the deltoid muscle, made a long incision on each side of it, so as to leave a kind of musculo-cutaneous bridge between them. The blade of a common saw, detached and passed under this bridge, and afterwards re-inserted into its handle, served to make the section below the pedicle of the tumor. As this saw could not be worked in a direction parallel with the axis of the humerus, it was necessary to make use of it a second time, and then to have recourse to a sort of file to equalize the surface of the bone. An abundant suppuration and accidents of quite a grave character supervened, but the cure ultimately was completely established. At the present time we should have to choose between three processes: One would consist in laying bare the tumor by cutting a large triangular or V flap, which should be raised up upon its base. After having applied pieces of pasteboard or linen to protect and depress the borders of the wound, the exostosis could be readily extirpated

\* The word *loupe* literally and anciently means a *wen*; and afterwards it became synonymous with *lipoma*, from whence it is probably derived. (See on Lipomatous Tumors, supra.) Its use in the case mentioned here and farther back, shows that it was applied to the reverse of wens and fatty tumors, viz., to those of an osseous, and also transparent texture. T.

by means of the ordinary saw, which it would be more advisable to work from below upwards than from above downwards. By a second process we might confine ourselves to cutting down upon the tumor itself, through the whole thickness of the tissues, from the apex of the acromion to the point of the deltoid, and then push back the lips of the wound to the right and to the left, to enable us to apply the saw upon the pedicle of the exostosis; but this process would not be applicable but to exostoses which make a very considerable projection, and which are elongated and have a narrow pedicle. The third, which is no other than the process of M. Jeffray, for the exsection of the elbow, and which M. Roux has proposed to put in practice, should at the present time be performed in the following manner: the two lateral incisions being made, we should carefully isolate the bridge and soft parts from the contour of the tumor. The cultellaire saw or one of the other hand-saws somewhat narrow, or even the osteotome of M. Charrière, would readily divide, either from one side to the other or from above downwards, the pedicle of the exostosis. No doubt also the articulated saw would answer the purpose equally well. All that would now remain, would be to thrust out and extract the foreign body through one of the openings destined for the passage of the instrument. But at the present day when we know how harmless is the division of muscular fibres, who would expose himself to the difficulties of this process, when that which I have pointed out above, renders the operation so easy and so simple? Exostoses are sometimes found also upon the shoulder. I have already mentioned, in speaking of exsection, or extirpation of the clavicle, that the history of a tumor of this kind which had two feet in circumference, and which weighed five pounds, and was a foot in length, had been given by Kulm. The tumor was removed, without, however, his mentioning very clearly whether the clavicle had to come away along with it at the same time.

#### § IV.

Lobstein (*Compte-Rendu du Musée de Strasbourg*, 1834, p. 61, no. 79,) says that an exostosis which was situated upon the *scapula* of a young man, was extirpated, and that the cure was effected in two months and a half. A child thirteen years of age, had upon the lower angle of the right shoulder blade, an exostosis of the size of a large egg, one half of which projected outwardly, and the other inwardly. The surgeon, M. W. Beaumont, (*Gaz. Méd.*, 1838, p. 778,) by excising with the saw or Liston's cutting pliers the angle of the *scapula*, which he caused to project between the *latissimus dorsi* and *serratus magnus* muscles, while raising up the arm of the patient, in this manner removed the tumor, and succeeded in obtaining a perfect cure.

#### § V.—The Foot.

Exostoses of the feet are met with especially upon the phalanges of the toes. André (*Observations sur les Maladies de l'Urêt.*, p. 410,) speaks of an exostosis of the size of a large cherry, which was situated upon the *great toe*, and which he was unable to remove until after having cauterized it several times with *eau mercurielle*.

Having elsewhere spoken (see Vol. I.) of sub-ungueal exostoses of the different toes, described in a particular manner by Dupuytren and M. Liston, (*Bull. de Férussac*, t. XIV., p. 255,) who with myself prefer in such cases amputation of the last phalanx to excision of the exostoses, I will refer the reader to those remarks. There have been met with on some of the bones of the metatarsus, exostoses which require a little further attention. It was in an instance of this kind that B. Bell (tome V., pp. 314, 315,) decided on extirpating completely one of these bones for an exostosis, which occupied its entire circumference. M. Herpin (*Constitution Médicale d'Indre-et-Loire*, p. 15, 1er trim. 1818,) speaks of an exostosis of three inches in circumference, which was situated upon the *first bone of the metatarsus*, and which he removed in the spring of 1806, by means of a small saw, after having laid bare its root by an elliptical incision. The bottom of the wound was cauterized with red hot iron, and the patient radically cured. There is frequently found upon the dorsal surface of the great toe, near its anterior extremity, a conical shaped exostosis, which it may become advisable to extirpate. A straight incision and one cut with the pliers, are generally all that is required for it. As, however, there is a mucous bursa there, which is sometimes continuous with the neighboring joint, it is advisable not to operate there without some degree of caution.

#### § VI.

In the leg, exostoses are found upon the fibula, tibia, and patella. M. A. Cooper relates that he saw a cartilaginous exostosis of the size of a chesnut, underneath the periosteum, an inch and a half below the head of the fibula. The extirpation of this tumor was performed by M. Leving, (A. Cooper, *Œuvr. Chir.*, transl. of Bertrand, t. I., p. 519,) who had recourse to the crucial incision, and divided the fibular nerve before removing the tumor with Hey's saw. The cure was effected in a month. A patient operated upon by V. Moreau, (communicated by M. Champion, who witnessed the fact,) was less fortunate. In a peasant girl, there was an exostosis of an eburnoid character (de nature éburnée) and large base, situated upon the antero-external side of the body of the tibia. This tumor was laid bare by means of a quadrilateral flap, and then removed by the aid of the gouge, chisel and mallet. This was in 1794; accidents supervened, and the patient died. In another case, a boy of fifteen or sixteen years of age, the exostosis, which was seated upon the spine of the tibia, had acquired the size of a Saint-Jean pear. The dissection of a triangular flap allowed of rasping the bone and embracing the exostosis in the aperture of a piece of tin plate, and thus exsecting it, without injuring the soft parts. The wound was united by first intention, and the cure, according to Bourqueneau, (*Annal. de la Soc. de Med. Prat. de Montpellier*, t. VII., p. 424,) was completed in the space of fifteen days. Finally, M. A. Cooper gives a case of exostosis with narrow base, situated underneath the periosteum at the antero-superior part of the tibia, and which, after having made an elliptical incision in the soft parts, was successfully removed by means of an amputating saw, directed from above downwards, and then from below upwards. A slight exfo-

liation, which took place subsequently, did not prevent a radical cure from being accomplished.

### § VII.—*The Patella.*

Vigarous, (*Œuvr. Chir. Prat.*, obs. 112, p. 557,) who has gathered in his work so many extraordinary observations, speaks of an exostosis or osseous steatoma, which grew on the anterior surface of the patella, and which was 25 inches in its circumference and was covered with four ulcers. Amputation of the thigh had been proposed, but Vigarous undertook to remove the tumor without interfering with the articulation. He effected this by means of several incisions and by sundry cuts of the saw. Some osseous laminæ exfoliated at a later period, but the operation, which consumed only fifteen minutes, was followed by complete success. As for the rest, it would appear from the description which this author gives of it, that this tumor, which was filled with soft matter, and osseous only upon its exterior, belonged rather to the class of degenerated hematic tumors than to that of exostoses properly so called.

### § VIII.

The *lower third of the femur* is perhaps the region of the osseous system where pediculated exostoses acquire the greatest volume, and are most frequently met with. I have seen them sometimes on the inner and sometimes on the outer condyle of this bone, and near the ham, and either acuminate or globular, and of the dimensions of half an inch to an inch in height. Those which more particularly require the attention of the surgeon, are such as have a tendency to develop themselves above the inner condyle, sometimes in front and sometimes behind. This is a kind of exostosis which is scarcely mentioned in authors, and which has this remarkable character, that the tumor is almost always found with the same features, and in the same place. M. A. Cooper, (*Œuvr. Chir.*, transl. of Bertrand, t. I., or translation of Chassaignac, p. 608,) who relates two examples, says, that in one of his patients the exostosis, which he denominates cartilaginous, was situated underneath the periosteum, a little above the inner condyle of the femur, and that it occasioned quite a considerable degree of pain. The exsection was made without implicating the muscles, by means of a saw which it was found necessary to fix by hooks, requiring afterwards the removal of some osseous asperities by means of cutting pincers. In the other case, the tumor, which was situated in the same place, and occasioned some inconvenience in the movements, was laid bare by an incision, which had to include some fibres of the sartorius muscle, through which the exostosis was extracted after Machel's saw, directed by the inventor himself, had divided its neck. I have already met, in six or seven instances, with the species of exostosis I have just described. In the first case it seemed as if the tuberosity of the inner condyle had been transformed into a long and strong coronoid process. The patient, who had been in this state for fifteen years, had become so habituated to it, that he would not hear anything said on the subject of an operation for his relief.

In the second case the tumor existed in a young man accustomed

to make voyages. It had the form and size of a small melon, and was situated underneath the vastus internus muscle, two or three inches above the articulation. The idea of an operation, and the apprehension of danger, have hitherto deterred the patient, who, however, suffers from it in no respect whatever.

The third case is that of a servant, seventeen years of age, who came in April, 1835, to the public consultation of the hospital of La Charité. The exostosis in him was precisely similar to that of the preceding patient, both in situation, form and volume.

In a fourth example, which I saw in 1836, the patient was forty-five years of age, and could not indicate the origin of his exostosis, which was also situated upon the inner side of the femur, at some inches above the knee.

It was in November, 1838, that I met with the fifth case. This last case was a man of about sixty years of age, who states that he has had it about thirty years, and that he attributes it to a badly-treated fracture of the thigh. There is every reason to believe, however, that there is nothing very authentic in this history. The abdominal limb in fact has no shortening, and the bone, in other respects, is perfectly regular. The tumor, which projects two inches and a half on the inside of the femur, which is three inches in diameter at its largest part, quite strongly bosselated, and situated at the union of the middle with the lower third of the thigh, exhibits at its root a contraction (*étranglement*) sufficiently marked to forbid the idea of imputing it to a morbid (*vicieux*) callus. A young boy, twelve years of age, had one of the size of a pullet's egg, a little lower down, which gave him no trouble, and for which he did nothing. The same was the case in a patient whom M. Macgloghlin took me to see in 1837.

It is a matter of surprise that we should so often meet with tumors of this description in such a region. None of the patients I saw were in any other respect annoyed except by the size, weight or deformity of the tumor. Thus there were no sufferings, no lancinating pains, no excoriations nor inflammations, nor adhesions of the skin or other tissues. So also did these patients, when I pointed out to them some of the dangers they might incur in undergoing an operation, come to the determination to retain their infirmity, and recoil from the operation, and perhaps they acted wisely. Ought we, however, on that account to say that supra-condyloid exostosis of the femur is absolutely incurable? No, certainly; but to remove it we have to resort to an operation, sometimes difficult, and almost always dangerous, whilst the disease in itself does not usually compromise the functions of the limb or the general health of the individual, and may remain stationary for an indefinite number of years, when it has once arrived at a certain period of its growth. The conclusion, therefore, in my own mind is, that I would not decide upon the removal of tumors of this description, unless, notwithstanding my representations, the patients should find themselves so much incommoded or annoyed as to make an urgent demand for relief, or unless such tumors should threaten to acquire too large a volume, or to undergo degeneration, or cause, in fine, actual pain, or serious functional derangement in the part. As for the rest, there is no other treatment for them but excision or extirpation, in which event many processes may be employed. Should

the exostosis be flattened and of small diameter, we lay it bare by means of a simple incision, commenced above and terminating below, and which ought to penetrate down to the bone. The cutting pliers, Liston's scissors, or one of the exsection saws, will then suffice for excising it from the femur. When it does not appear practicable to isolate the whole contour of the tumor by means of a straight incision, we may then choose between the crucial incision, that of the T, the double vertical incision of Jeffray, or the semilunar. The crucial incision would have no other inconvenience than that of completely dividing, and in two opposite directions, all the fibres of the vastus internus muscle. Nevertheless this difficulty ought not, at the present day, to deter us, if by that means we should render the operation more easy, inasmuch as the section of the muscular layers involves in reality but very slight inconvenience. The T incision might be made in such manner that its horizontal branch could be placed in front or behind the tumor, almost indifferently. I should, however, prefer to place it in front, in order that its vertical branch might be made to fall upon the inner border of the ham, and permit the two flaps which it circumscribed to be reversed, the one downwards and the other upwards and backwards. The incision with two parallel branches, one situated in front and the other behind, so as to circumscribe a bridge of soft parts upon the exostosis, has in this region still greater inconveniences than for sub-deltoidal tumors of the humerus. M. Roux, who made trial of it in the young servant whom I have mentioned farther back, was obliged to divide the soft parts transversely through their middle, transforming it in this manner into two quadrangular flaps. Besides creating in this manner embarrassment in the section of the tumor, we expose ourselves moreover to the risk of not being able afterwards to disengage it from among the muscles, and effect its complete extraction. It is therefore more prudent to resort at first to the semilunar incision. This incision, whose free border should be turned inwards, would circumscribe a flap, which should be reversed from behind forwards, and would lay bare the whole of the exostosis. An assistant drawing this flap upon its base and outwards, while another assistant would hold apart the inner lip of the wound backwards and inwards, and while the limb was held in semi-flexion, and lying on its outer side, would enable the surgeon to carry any saw whatever very near the femur, and to divide the neck of the exostosis. If there should remain any asperities or osseous inequalities at the bottom of the wound, nothing would be more easy than to remove them by means of the chisel, gouge and mallet, or by the aid of the rasp or the concave rowel saw of M. Martin. We might also confine ourselves to a straight incision, placed on one of the sides of the tumor, and which should be sufficiently long to enable us to separate its borders wide apart. The osteotome of M. Heine, or the saw of M. Charrière, or even that of Aitken, introduced by this means upon the pedicle of the tumor, would evidently enable us to detach it in the greater number of patients; and everything shows that by giving the incision a certain extent, it would give free egress to the foreign body. It is perceived, moreover, that the process in these cases ought to vary according to the size, form and actual seat of the tumor, or the particular taste and practice of the

surgeon. I would only remark, however, that in general the semilunar incision is the one that should be adopted by preference. Up to the present time, this operation has not been performed sufficiently often to enable us to appreciate exactly either its dangers or harmlessness. The two patients of M. A. Cooper, did not recover without causing some uneasiness; and that of M. Roux, who, though he was young, of excellent constitution, and in perfect health, ultimately perished. The surgeon, being obliged to penetrate down to the bone, necessarily arrives beneath the fascia lata. Being unable to detach the exostosis without more or less contusing the neighboring tissues, and without making a wound whose bottom is hard and more or less rugated, he can scarcely count on immediate reunion. But if the inflammation and suppuration, which in such cases would almost inevitably supervene, should take on a diffused character and extend downwards towards the ham, and upwards into the body of the thigh, they would soon constitute one of those forms of phlegmonous erysipelas, or diffused phlegmons, which are the most formidable that can be imagined. I would therefore lay it down as a precept, whenever immediate reunion, and without suppuration, cannot succeed, that we should not attempt the cure of the wound by first intention, but confine ourselves to keeping it slightly open by means of small balls of lint, until it is perfectly cleansed, and that there has been formed the pyogenic membrane and cellulo-vascular vermilion surface.

---

## CHAPTER XII.

### THE LIGATURE IN MASS.

We have already seen in the preceding volumes under how many forms the ligature is employed in surgery. Useful for uniting certain wounds, almost indispensable around vessels, to arrest the blood in amputations, for wounds of arteries, aneurisms, and most bloody operations, it is, so to speak, called for as often as we take the bistoury in our hands. But in such cases the ligature includes and constricts only the vascular canal, whose orifice or calibre we wish to close. But there are a class of operations in which we apply the ligature in a different way. In these we no longer apply it on a distinct vessel at the bottom of any wound, nor is it now designed to repress the effusion of blood; its object here is, by strangulating the parts, to mortify, sometimes, quite a considerable portion of them left outside of it. It is to this last kind of constriction that the title, in our times, is given of *ligature in mass*. It is thus that polypus has been treated at every epoch, whether situated in the nose, the womb, or rectum, or even in the ear. Most pediculated tumors have also been treated at every period of science by the ligature in mass. Even amputation of the limbs has been sometimes performed in this manner. I have related several examples of this kind under the chapter on Amputations in general. When castration is performed, it is allowable to embrace the whole of the testicular cord in a ligature, and to

strangulate it in mass. The ligature for fistula in ano, so frequently employed in the last century, was nothing more than the ligature in mass. We see by these examples under what circumstances the strangulation of the parts ought in reality to receive the name of ligature in mass, and to how many and to what kind of operations this description of remedy is applicable. To effect it the surgeon may make use of all the different kinds of ligatures imaginable; those of silk, thread, linen packthread, cord, fibres of plants, lead, silver, gold, platina, and maillechort, rendered flexible by the various means known in the arts, furnish the same resources for the ligature in mass as for the simple ligature of vessels or for sutures. Nevertheless, we cannot indifferently employ any one of these substances in preference to another. Should we require a ligature somewhat small in size, and which should be at the same time very supple and strong, the silk ought to be preferred. If it is required to effect a firm constriction of a soft tissue with a root somewhat large, a ligature of hemp, made by twisting three, four or five strands of simple thread, presents the most advantages. Packthread, which might be substituted for it, has the inconvenience of adapting itself with less facility to the bottom of the parts, and of untying itself too easily. It is advisable, moreover, in place of besmearing them with soap, as some persons have recommended, to rub the strands of the thread or packthread with wax, which prevents, or at least diminishes, its tendency to slip. Tissues of plants or ligatures of linen ought not to be employed unless none better can be obtained. As to metallic ligatures, however pliant some may consider them, they never possess the flexibility of thread, and cannot obtain the same generalization in practice. They consequently ought not to be preferred, unless there is necessity of a very great degree of constriction, or to put ourselves on our guard against the dissolution, putrefaction, or physical alterations of the ligature. There are also some cases where substances, which would be susceptible of solution and absorption by the living organs, might have an advantage. Thus to strangulate an intestine, either transversely or on its side, and in such manner as to return it immediately afterwards into the belly, it would be a precious advantage to have the use of ligatures which, as soon as they were applied, would cease to act as a foreign body. For this purpose there has been used silk in its natural or raw state, deerskin, chamois leather, gold beaters' skin, catgut, &c. But in addition to the fact that ligatures or threads fabricated out of these substances, are deficient in solidity, they have moreover the inconvenience of not being absorbed, except in a few cases, without exciting inflammation or suppuration. The ligature in mass is not applied in all cases in the same manner. If in some cases we limit ourselves to encircling the part by placing the ligature immediately upon the skin without any previous incision, we on other occasions commence by dividing the integuments upon the same circle which is to receive the ligature. These two modifications of the ligature in mass were known at a very ancient period. In the method known as M. Mayor's, and which, since the time of Hippocrates, all surgeons occasionally employ, we commence by laying bare and dissecting the parts which it is our intention to destroy, and it is not

until after we have isolated them nearly down to their root, that we surround them with the ligature and strangulate them. This last method is daily applied, as it has been for ages past, for the extirpation of tumors of the axilla after the removal of cancers of the breast, also in the ligature of the spermatic cord, etc. The various modifications of the ligature in mass are nevertheless all classified under two general methods, viz: the ligature without previous dissection of the integuments, and the ligature after the dissection of the tumor.

#### ARTICLE I.—LIGATURE WITHOUT DISSECTION.

The ligature in mass, without previous dissection, comprises three varieties: the thread or ligature is applied on the integuments without any other precaution, or after a circular incision of the skin, and sometimes also after having cut through the tissues behind the root of the body which is to be destroyed. The ligature upon the integuments, whether they are cutaneous or mucous, is effected by means of all the different kinds mentioned above. Some surgeons of former times, and some practitioners of the ancient academy of surgery, had proposed in such cases to saturate the ligature with some caustic matter, in order, they said, that it might more rapidly cut through the tissues. This precaution, which rendered the operation obviously more painful, augmented the inflammation, and did not sensibly hasten the fall of the ligature, and which moreover rendered it more brittle, is no longer employed in our time. It is by a mechanical action, and not by its chemical properties that the ligature, thus applied, is to produce its effects. This description of ligature, which is applicable to cutaneous tumors, whether they are fibrous, vascular or horny, when they have a narrow root and are easily raised up, is equally applicable to bodies that are fibrous, mucous, or of any other character, which are found in the interior of the mucous cavities. To accomplish it we require a ligature properly prepared, and of a strength, breadth and thickness proportioned to the volume of the tumor, or the degree of constriction to be used. The ligature being arranged, the surgeon causes the tumor to be raised up in such manner as to surround its root a little behind it, and upon the sound tissues. If the pedicle of this tumor is purely cutaneous, there is no danger in strangulating it. When it is rather more cylindrical or conical than dilated (*renflée*), we may limit ourselves to applying the ligature upon its neck without making the least traction upon it; on the contrary it may be advantageous to raise it up with a certain degree of force while we are applying the ligature, if we do not wish to incur the risk of leaving behind a certain portion of the degenerated tissues.

It sometimes happens, that, in order to prevent the ligature from slipping, from the integuments towards to the tumor, we are obliged to give it certain points d'appui on the confines of the diseased region. It is in this manner that an erigne, a tenaculum, or a hook forceps with very convex teeth, sometimes becomes necessary. The tumor being drawn upon by an instrument of this description, obliges the ligature to glide backwards, in proportion as it is tightened. As it is

sometimes necessary that this last precaution should be rendered permanent, it has been proposed to pass, at first, a simple metallic stem, or two similar stems crosswise, under the root of the tumor, in the manner I proceed, and as M. Davat has done, for the ligature in mass, on varices. These stems, having transfixed the tissues firmly, retain the ligature, which is placed behind them; in this manner we strangle without any great degree of difficulty, and circularly, non-pediculated tumors. I have mentioned farther back, what has been obtained from this description of ligature, in the treatment of erectile tumors. As it is difficult to strangle the parts completely, when they have a considerable degree of thickness, it was readily suggested, that we should embrace a portion only of the base of large sized tumors with each ligature, to pass two, three or four ligatures in order afterwards to mortify separately each of the parts, or one of the four triangles of the pedicle, when the threads have perforated it crosswise. Should it be desired to apply a double ligature, we take a long waxed thread, with a needle, pierced near its point, and having a handle, or a long common needle slightly curved, or a probe, inserted in a canula which a trochar had previously enabled us to plunge through the tumor. We pass the thread behind the root of this last. Having immediately cut it near the needle, or disengaged it from the eye which conducted it, the thread is instantly un-doubled; we then seize hold of one of its halves which is tied into a knot on one side, and then do the same with the other, on the opposite side, taking care to tighten them in a proper manner. In this way, the ligature strangles only a portion of the mass. As it acts, moreover, from within outwards, it produces as much effect as if the tumor was only half the size that it is. If, as M. Warren (*on Tumors*, etc., p. 418) appears to have often done, we should incline to divide the tumor into four parts, by means of threads, it would be advisable to insert the four ligatures in succession, and to give the preference to the needle of J. L. Petit. Each thread would thus circumscribe a quarter of a circle, and the entire circumference of the tumor would finally become strangulated. Finally, it would also be practicable to imitate Sommé, who, wishing to divide the bridle of a pseudarthrosis, plunged in his ligature, and brought it out by the same opening, after having passed it around the tissues to be divided, a method, which, as I have elsewhere said, appears to have also been made trial of for varices. We should, therefore, insert by puncture, and sub-cutaneously, by means of a needle slightly curved, or any other instrument, a ligature upon the contour of one of the halves of the mass. Brought again, by a second puncture, to the opposite extremity of the great diameter of the tumor, the ligature would be conducted in the same manner upon the other side, and brought out at its point of departure. We should, in this way, procure a circular constriction, which would in no respect interfere with the integuments, and perform an operation entirely under the skin. A last mode of strangulation, without previous dissection, and which has already been employed by some surgeons, by M. Manec among others, consists in introducing as far as the centre of the tumor, four metallic stems, each armed with a hook, which, darting through it in the manner of a spring, afterwards divides the tissues from the cen-

tre to the circumference by means of a quick screw adjusted to their free extremity.

## ARTICLE II.—LIGATURE IN MASS, WITH DISSECTION.

The surgeon has often a good deal of embarrassment when completing the separation of tumors that are deeply situated, or organs whose pedicle is nourished by numerous vessels, which cannot be seized without difficulty, or that are of large size. This is seen in the extirpation of the tongue, the removal of cancerous tonsils, the thyroid body when degenerated, and in most of the tumors of the neck, axilla, groin, &c. It is easy to be conceived, that the surgeon, who has to extirpate a cancerous tonsil or tongue, must necessarily be intimidated with the hemorrhage which may result from such an operation. All extirpations of goitre have also been considered formidable from the same danger. M. Mayor, (*Essai sur la Ligature*, etc., Lausanne, 1821 ; *Essai sur la Lig. en Masse*, Paris, 1826,) in giving more importance than any other person to this inconvenience in bloody operations, has suggested that a ligature which would embrace the root of the tumor, would enable us to penetrate deeper down than with the bistoury, while offering, at the same time, to the operator all the security desirable. So that the ligature in mass, with previous dissection, and which was formerly but seldom had recourse to, is now in sufficiently general use. It is effected, moreover, with the same substances, and by the same processes, as the preceding method. Thus, in order to accomplish this, we may make use of threads, of silk, hemp or flax, ligatures of linen, packthread, or cord, wires of lead, silver, or other flexible metal or the different kinds obtained from animal tissues. In the same way as for the ligature in mass, externally, we might imbue the thread with caustic or medicated material, or apply it without any other precaution, upon the root of the tumor, and prevent its slipping by the various means employed to arrest the knot in the ligature upon an artery. If the body to be strangulated is voluminous, it is advisable, at first, to perforate it with a double ligature, the two portions of which are afterwards separated, in order to form a distinct circle, applied to each half of the pedicle we wish to mortify. Nothing, moreover, would prevent our dividing the root of the tumor into four portions, by means of four separate ligatures ; but the ligature in mass, with metallic wires, would be applicable after dissection only, to tumors whose entire contour and root passed beyond the level of the integuments. If, however, in order to effect its strangulation in a proper manner, it should be thought advisable to insert the metallic stems crosswise, through its root, it would still be practicable to recur to this, provided we took care to withdraw them shortly after, that is to say, as soon as the ligature had cut sufficiently deep into the tissues to prevent it from any longer having a disposition to slip.

## ARTICLE III.—MANNER OF EFFECTING STRANGULATION BY THE MASS.

The object here is to interrupt all kind of circulation and physiological action in the mass whose pedicle is constricted. The

better way would then appear to be, to strangulate the parts at first as powerfully as possible. Nevertheless, the ligature in mass is sometimes employed in such manner as to cut or strangulate only by degrees, the organs which it embraces. If the ligature has but little volume and acts insensibly, it may happen that the first organic layers cut by it do not mortify, but even reunite external to it, so as to imprison it, before its action has been brought to bear upon the tissues which are deeper situated. M. Mirault noticed this in a case of strangulation of the tongue; what I myself have also seen, and what J. L. Petit had already noticed after a ligature in mass upon the testicular cord; which result I have witnessed also in the case of a child who had strangulated the penis with a simple thread. This species of constriction, therefore, is for the most part very uncertain. Nevertheless, there might be cases where it would be advisable, provided that by thus cutting through the tissues by degrees without mortifying them, some prospect might be obtained of effecting a radical change (modifier profondément,) in their morbid condition. We shall find, in fact, in speaking of operations performed upon the tongue, that the patient treated in this manner by M. Mirault, ultimately recovered of his cancer. If, however, the strangulation at first is sufficiently powerful to arrest the passage of the fluids, the tumor, which is immediately deprived of its vitality, first becomes blue and livid, and then softens, shrinks and loses its volume. From this it happens that the ligature is no sooner sufficiently tightened, than it slips and is displaced, and no longer makes any constriction. In this point of view, practitioners in my judgment appear to have examined but one of the points of the question. If the ligature changes place before the entire physiological circulation in the tumor has been suspended, it is clear that life may be re-established and that our object will be defeated. If, however, this displacement does not take place until at the expiration of 24 hours, or in consequence of the shrinking of the tissues, our purpose, nevertheless will be attained. After this first result, however, the consequences will be the same, whether the ligature remains or is removed. Every thing existing external to the ligature is effectually mortified, represents an eschar, and acts in the same way as a foreign body which must necessarily come away through the eliminating powers of the system. We see in these cases a line of demarcation established between the living and dead parts, while a process takes place in every respect analogous to that which detaches the eschars from a burn. For which reasons, my rule is to remove the ligature at the end of one or two days, when it incommodes, or when it is not my design to increase its constriction from day to day. As to the manner of performing this strangulation, it presents a certain number of modifications.

#### § I.—*Simple Strangulation.*

Whether the ligature to be applied is to be external or deep-seated, we nevertheless frequently confine ourselves to strangulating the pedicle of the tumor by a double or even a single knot, in the same way as in tying an artery. Nevertheless, as it is almost always necessary to constrict the parts as strongly as possible, the first knot requires to

be firmly secured while we are adjusting the other. To effect this we have three resources: 1. An assistant holds the extremity of one of his fingers accurately placed upon the crossing of the threads, while the surgeon prepares the second knot of the ligature; 2. should the finger be found too large for this purpose, we substitute for it the blunt extremity of any metallic instrument whatever; 3. or what is still more secure, we firmly embrace the first knot with the point of a forceps. Still another means consists after the first knot is made, in carrying the two portions of the ligature again around the tumor, in order to knot and tighten them in the same manner upon the opposite side. Whatever mode is adopted, it is advisable to cut one or both of the free portions of the ligature near the knot. We cut both, should nothing prevent our seizing hold of, and dividing the knot at its place, when we judge proper. We leave one, on the contrary, when we consider it advisable that we should have a guide to remove the ligature at a proper time. If the ligature is intended to be temporary, we might, after having tightened it, adjust its first knot by a simple rosette (bow-knot). By this means we may readily withdraw the ligature at the end of one, two, three, or four days, and disembarass the parts without dividing anything.

## § II.

In place of this sudden strangulation, we sometimes have recourse to a graduated constriction, a constriction which, notwithstanding the shrinking and withering of the divided parts, shall act in such manner that the strangulation of those which remain, is not at all relaxed, but continued up to the time of their complete separation. For this purpose, quite a number of different modes have been devised. One of them is so ingeniously arranged that the ligature tightens itself in proportion as the tissues recede. To accomplish this M. Pelletan has contrived an instrument more ingenious than those of Levret, and which is represented by a stem with a double canal, having at its free extremity a sufficiently powerful spring, which receives the extremities of the ligature which have been previously passed around the tumor, and which constantly tends to make traction upon them, (*les entrainer*). Others have invented ligatures whose constriction may be augmented or diminished at pleasure. All the kinds of knot-tighteners (*serre-nœuds*) nearly, belong to this description. Whether, in fact, we make use of the *serre-nœud* of Levret, that of Deschamps, Desault, Dubois, or even the simple bow-knot, we may, nevertheless, renew at pleasure the degree of strangulation we have at first produced. When we have surrounded the tumor with a metallic thread, it will be sufficient to twist the two free portions in a spiral manner around each other, if we wish to make daily increase of the constriction. The most ingenious instruments we possess of this kind are those of M. Bouchet, M. Mayor, M. Graefé, and Dupuytren.

The knot-tightener of M. Bouchet is a sort of rundlet traversed by the two threads, and around which they are attached in order to be shortened to the degree desired. M. Mayor, reviving an idea formerly thrown out by Roderic, has proposed to pass the two united extremities of the noose of the ligature which surrounds the tumor,

through a series of beads or small balls of wood, ivory, horn, bone, silver or any other substance, in the manner of stringing the beads of the Paternoster. The first of these beads being pierced with two holes, allows of tightening the two halves of the ligature strongly upon the last, and of forcing the other in a proper manner against the tumor. To do this with still greater ease, we may replace the outer half of this chain of beads by a metallic or ivory tube, and make use of a small winch (*treuil*) to receive the extremities of the ligature. We have, by this means, a ligature which terminates in a flexible stem, which adapts itself with facility to the parts, and interposes no obstacle to the gradual strangulation of the tissues. The knot-tightener of M. Graefe, as modified by Dupuytren, receives by one of its extremities the double thread of the ligature. This ligature is then attached by several turns to a small lateral nut, (*écrou*), which is separated from or approximated to the wings or outer extremity of the instrument at pleasure, by means of a quick-screw, (*vis de rappel*.) (See article, *infra*, on *Polypi of the nose, uterus, &c.*)

#### ARTICLE IV.—APPRECIATION.

The ligature in mass, applied exclusively and alone, and adjusted by a common knot as near as possible to the root of the tumor, more frequently answers the purpose than is generally supposed. It is in fact, in most cases, not at all necessary, as some think, to renew the constriction and tighten the ligature daily. I have seen enormous tumors yield to this kind of constriction kept up for twenty-four hours, or even in some cases for only twelve hours. An immense polypus of the pharynx and nasal fossæ thus strangulated for the space of some days, and divested of its ligature a long time before it had been completely cut through, nevertheless separated at its root. How often have we not seen polypi of the uterus, treated by the ligature, detach themselves beyond the point which had been touched (*touché*) by the thread, and although the constriction had been actually maintained only for the space of a few hours! Nevertheless, this species of strangulation is not as suitable as the others, when we have to include a great mass of tissue. It is in such cases that partial or progressive strangulation merits the preference. Partial strangulation by means of threads passed through the tumor, acts more promptly and with more certainty than the simple ligature; but it is applicable only to external tumors, and would not be adapted to those whose pedicle includes voluminous vascular trunks, or large sized nerves. Here, therefore, we should make use of gradual strangulation. Underneath the skin this last mode would, at first, present great difficulties, and would not probably succeed until after having transformed the tumor into a vast abscess, at the same time without giving assurance that the integuments would be preserved. The process of M. Manec is, undoubtedly, the most difficult and most embarrassing, and the least certain of all. By means of knot-tighteners, should we use that of M. Pelletan, the results we would produce could only be imperfect and incomplete. The instrument of M. Graefe, when a straight and inflexible stem, is not attended

with any serious inconvenience ; or on the contrary, the chaplet of Roderic, as improved by M. Mayor, may enable us to dispense with the others, and presents all the requirements of force and simplicity desirable. As for the rest, it is not to be forgotten, that the operation is practicable with all these instruments and by all these processes ; which, nevertheless, does not exempt me from adding that the ligature in mass never should be the method of election, when it is practicable to employ the cutting instrument without manifest danger. The ligature in mass, used in the manner I have described, causes the separation of the tissues at the expiration of a period of time, which varies between three or four days and two or three weeks.

During all this period the tumor passes into a state of putrefaction, is decomposed, and emits an odor which is usually offensive, together with discharges which possess a certain degree of acrimony. Hence the extremely unpleasant consequences, both to the patient and those who approach him ; and hence the real dangers which may result from this state of things by means of resorption, infection or poisoning. I have, therefore, been in the habit, when I have employed this operation, of excising from a half an inch to an inch of all that portion of the ligature which was found outside, as soon as the circulation appeared to me to have been sufficiently destroyed in the centre of the tumor. I remove the ligature itself at the end of four or five days, when this first excision convinces me that there no longer remains any degree of vitality in the circle of the constriction. The patients are thus relieved from an actual pestilential ulcer, (foyer,) and they have nothing more to undergo than the eliminative process from all the different points, similar to that which détaches the eschars from a burn, contusion, or gangrene. It is nevertheless true, however, that with the exception of a small number of cases, the ligature in mass will always be the favorite operation with surgeons who have but little experience with the knife, or not much confidence in their anatomical knowledge, or the steadiness (*sûreté*) of their hand. No one, however, as I think, would undertake to contend, that an operation finished in a few minutes, and which leaves a fresh and living wound, can be where all other things are equal, less advantageous than an operation which cannot be completed in less than from eight to fifteen days, which is accompanied with all the phenomena of gangrene, and the wound made by which does not begin to become cleansed, until at a period when that of the other may be perfectly cicatrized.

---

## CHAPTER XIII.

### FOREIGN BODIES.

Numerous foreign substances, and of different kinds, may exist in the human body, and require the intervention of surgery. Some-

times these substances come from without, and at other times form in the midst of the parts themselves. The sequestra of bones, eschars within the soft parts, certain accidental productions, different sorts of calculous concretions, the decomposed products of fecundation, whether uterine or extra-uterine, &c. &c., belong to the last-named class. Substances derived from three kingdoms of nature, and which, having once entered into the living cavities or tissues, are arrested there as anomalous, and remain there as morbid causes, are to be enumerated under the first class. The organs most exposed to these kinds of accidents, are the ear, frontal sinus, eye, nares, mouth, maxillary sinus, the air passages, œsophagus, urethra and bladder, vagina and womb, and the rectum and intestines in general. It will be while examining the operations required for the diseases of these different organs or regions (appareils) that the occasion will present of speaking, also, of the foreign bodies which are found in them. I do not therefore intend, at this moment, to treat of other foreign bodies than those that are attached to, or formed upon other regions of the animal economy.

## ARTICLE I.—TRUNK.

### § I.—*The Head.*

In this series we shall find foreign bodies in the head, face, chest and abdomen. Projectiles thrown by powder, as powder itself, lead, and especially balls, langridge (mitraille) discharges from bombs, or howitzers, biscayans, and even small bullets, are frequently found there. Then come pieces (tiges) and fragments of metal, wood, wadding, clothing, flints, portions of glass, &c. There are no regions where these different foreign bodies have not sometimes been encountered. A ball which was found near the gullet, (*Transact. Phil.*, 1738, p. 449, art. 6,) had entered there by passing through the lower jaw and tongue a year before. A dice (dé) entered from the pharynx of a child into the pterygoid fossa, (Parrish, *Encyclogr. des Sc. Méd.*, 1836, p. 321.) I have removed, through the mouth, a ball which a boy, aged fifteen years, had driven by the discharge of a pistol into the body of the fourth cervical vertebra. Marchettis (Bonet, *Corps de Médecine*, t. III., part 2, obs. 25, p. 230,) speaks of the fragment of a fan, which having been introduced through the orbit into the upper maxillary bone, made its way out, and was extracted in part externally, and partly through the palate, at the expiration of three months. A man, fifty years of age, whose case is given by Muys, (Planque, *Bibl.*, t. I., p. 43, in 4°.) had in an abscess below the ear, a portion of pipe which he had forced into his throat six months before. Percy (*Manuel du Chirurgien d'Armée*, p. 109,) relates a great number of cases where various foreign bodies had in this way become lodged in the head. A patient mentioned by De La Motte, (*Tr. Compl.*, t. I., p. 718, ob. 205,) received a sword thrust between the gum and nose, and the weapon breaking, perforated near the ear and remained of the thickness of a farthing external to its place of entrance. The wound cicatrized over it, suppuration took place near the ear, and no attempt was made to extract the foreign body. A man, in despair from being paralyzed, discharged a pistol into his

mouth. The following day he told me he had felt the ball descending into the stomach, and he was no longer paralyzed! Watching the symptoms, I noticed, on the eighth day, a slight degree of emphysema over the left eye. I cut down and extracted the ball, which had shattered and contused the orbital arch. This patient was cured both of his wound and paralysis. In the case of a wound, related by Donnadieu, (*Anc. Journ. de Méd.*, t. VIII., p. 549,) the point of a copper spindle remained for thirteen months fixed in the cheek and one of the jaws. At first its presence was not noticed. A sinuous ulcer finally disclosed it, when the metallic point was extracted, and the cure took place. Courgeolles (*Ib.*, p. 551,) makes mention of a fragment of wood, which having become implanted or imprisoned in the bone near the supra-orbital notch for the space of fourteen years, had produced no other result than a warty excrescence, which successively disappeared and returned without the patient taking any farther notice of it. In F. de Hilden, (Bonet, *Corps de Méd.*, p. 160,) we find the history of a ball which had remained for six months between the cranium and dura mater. A patient of Morand, (*Opusc. de Chir.*, p. 159, 1re partie,) who died at the expiration of nine months, presented a similar fact. Analogous cases have been related by a great number of surgeons, and especially by M. Larrey, who also speaks of ram-rods traversing the cranium without causing immediate death. An example of this kind has just been published by M. Zedleg, (*Gaz. Méd.*, 1838, p. 379.) A ball had been retained for eighteen years above the orbit, in the substance of the frontal bone on the right side, and the patient, who in other respects had been in quite good health up to that time, died of apoplexy. Thomassin, (*Extraction des Corps étrangers*, etc., p. 16,) in the case of a child aged twelve years, saw an arrow forced through and through the apex of the cranium, but which, however, was extracted, with a successful result. A patient who had carried for the space of four months a similar body in the brain, was cured by M. Majault, the father, (*Mém. de l'Acad. de la Chir.*, t. I., p. 316, in 4°.) but Majault, the son, operating at the expiration of eleven years for a similar lesion, lost his patient on the third day, (*Journ. de Méd.*, t. XLI., p. 82.) Solingius (V. D. Wiel, cent. 11.) was more fortunate, and succeeded in extracting from the cranium a portion of the blade of a sword, which had broken there after having entered by the great angle of the eye. The point of a poignard, which had broken in the cranium, and which at first could not be extracted, became detached almost of itself at a later period, (Bartholin, cent. 4.) A portion of the stock of a musket, which had been for two months in the brain without causing any accidents, after being extracted, was followed by death, (*Journ. de Méd.*, t. I., p. 242, obs. 8.) [See remarkable and recent cases of these injuries in our notes under *Trephining*, Vol. II.]

## § II.—Thorax.

If we pass from the head to the chest, we shall find that an ear of wheat, (A. Paré, liv. 25, chap. 16,—Bally, *Revue Méd. Franc. et étrang.*, etc.) and needles and pins swallowed by accident, have made their way through the lungs, and finally, after having produced

an abscess there, and sometimes even without any previous morbid changes, have finally shown themselves under the skin. Every body knows the case related by Gérard of a knife blade which had become fixed in a rib in such manner as to project into the interior of the thorax more than from the outside of the rib. Bidloo, Bagieu, Desport and M. Terrin, mention cases where they had to extract balls from between the ribs, where they had either entered or were making their egress. Wherter, (*Journ. Gén. de Méd.*, t. LXIX., p. 423,) on the authority of the military surgeon Hunter, mentions a biscayan of three ounces which, after having fractured the ribs, lost itself at the depth of five inches in the lungs. The fragments of broken bones were exsected, the foreign body extracted, and the patient cured; but this account is so problematical that we may place it by the side of that which mentions a ball of seven pounds' weight which had travelled into the haunch! Broussais (*Histoire des Phlegmasies Chroniques*, 2e edit.) speaks of a soldier who died at the expiration of fifteen or twenty years, with a ball in the lungs, without any person having suspected it; and Thomassin (op. cit., p. 96,) relates that he found a ball in the right lung of a man who died at the expiration of three weeks from wounds disconnected with this last. Briot (*Hist. de la Chir. Milit.*, p. 97,) cites a case where a ball, after having passed through the scapula, became wedged in between two ribs.

Having dilated the wounds and glided the beak of a spatula behind the foreign body, its extraction was effected while the patient made a strong inspiration. In the memoirs of M. Larrey, (*Ibid.*, t. IV., p. 259,) we find the case of a ball, weighing ten drachms (gros), which had perforated the thorax between the eighth and ninth ribs. The surgeon could not effect its extraction until after having notched out, by means of a blunt-pointed bistoury, the whole breadth of the lower rib, down to within two lines above its arterial border, to such extent that the patient, in a sudden flexion of the trunk, fractured the rest of this bone, wounded the intercostal artery and produced a hemorrhage, which was finally restrained, but not without difficulty, by means of the process of Desault. The same surgeon had, moreover, some time previously, extracted a ball weighing six drachms without previous exsection of the bones. A girl who received the discharge of a pistol in her back, died on the twentieth day. The ball which lacerated (rompu) says F. Plater (Thomassin, op. cit.) the spinal marrow had implanted itself into the body of the ninth vertebra. M. Burnes (*Archiv. Gén. de Méd.*, t. XXVIII., p. 411) speaks of a fork which was extracted from the back of a patient without its being known how it had entered there. Foreign bodies of another description also, have quite frequently been found in the body (epaisseur) of the chest. I will relate here two singular cases. A convict died of a visceral affection at the hospital of Rochefort (Guillon, *Presse Médicale*, t. I., p. 151.) In this man a *foil* (fleuret) was found in the chest which had transfixied it completely, one of the extremities being in the substance of one of the ribs, and the other in the body of a vertebra, while the middle portion, covered with stalactites, was enclosed in the body of the lungs. It was ascertained that the wound had been made fifteen years before, and no one sus-

pected that a foreign body of such a character existed in the thorax of the patient. A case not less remarkable, but in which the consequences were more disastrous, was presented at La Charité, in 1836. While on exercise, an officer of the National Guards, of Paris, received in his back a musket ram-rod of large calibre. This rod penetrated to the depth of fifteen inches, taking an oblique direction from the left dorsal region to the right breast. Traction made by a number of surgeons, and men of great strength, near Sceaux, where the accident happened, could not in the least degree move the foreign body. I was enabled in the evening to examine this patient at the hospital, whither he had been removed. After the facts communicated to me, and after comparative measurements of the remaining portion of the ram-rod and the musket, with another ram-rod of similar calibre; and after having struck several times upon the metallic point, which projected about five inches from the dorsal region, I had no doubt that it had perforated through and through the thorax. No serious accident had yet occurred, and the patient suffered but little. What in such a case was to be done? The removal of the rod might give rise to a hemorrhage and effusion of blood which might suddenly prove mortal; there was room for apprehending that the aorta, vena cava, or even the heart might have been transfixated (*embrochés*)—[this conjecture scarcely seems supportable, T.]—and that in removing from them the species of plug which had shut up their perforation, the sources of life would have been instantly extinguished. But by leaving it in its place could we, on the other hand, hope that the wounded man would survive? For how could we conceive that a rod like this, traversing organs so important, would not soon give birth to accidents that would prove speedily fatal. The case of M. Guillon was not then known to me, and if it had been it would have strengthened me in the step I deemed it proper to take, which was that of delay.

This course, moreover, was one of necessity. Our surgical resources, rich as they already are, have nothing which would enable us to extract a body of this description. I hoped that the process of supuration taking place around the foreign body, would soon render it movable, and allow of its being removed, at the same time that it would obliterate the vessels, if any had, in reality, been wounded. At all events, I caused to be constructed, by the ingenious artist, Charrière, an instrument which would have carried out my views, had not the patient, in spite of the most rigid antiphlogistic treatment, succumbed at the expiration of four days, almost suddenly, without having given any positive evidences of pneumonia or effusions in the chest. The opening of the dead body disclosed to us, that the rod had traversed one of the dorsal vertebræ, at a line in front of the spinal canal; that afterwards, grazing the vena cava ascendens, and passing under the base of the heart, it had passed through the lung to arrive between the ribs under the right breast, where it still remained. The larger vessels and the heart were intact. The lung, though slightly engorged, was not inflamed; it would appear that death had been caused by the effusion of a certain quantity of blood into the bronchial tubes, (*les bronches*), laid open in the track of the rod. I then made an essay with the instrument of

M. Charrière, and we found that it would have perfectly fulfilled the indication. This instrument is composed of a large metallic plate, which was intended to have its support upon the back, after having allowed the projecting portion of the rod to pass through it. This last being admitted into a solid tunnel, or sort of socket, itself sustained upon the plate mentioned, furnished support to a nut, by which the action would have been made upon the foreign body without any unsteadiness, and in a gentle manner, after the manner of a quick screw from before backwards, permitting all the force requisite to be used, and that without exposing to any kind of concussion. If this instrument, which could not be completed until the day the patient died, had been accessible at the first, perhaps I should have had recourse to it: would the patient, in that case, have survived? This is precisely the question which will always cause the greater number of surgeons to hesitate under such circumstances. I will nevertheless add, that hereafter, notwithstanding the case published by M. Guillon, and the defence of it by M. Larrey, I would adopt the resolution of extracting the foreign body, rather than abandon its dislodgement to the resources of the organism.

[The difficulty in having at our disposal the ingenious contrivance mentioned, is that such accidents are too rare to have these apparatus on hand, already fabricated. The principle, however, could be very readily adapted, we should think, in a few minutes, to a temporary construction. This case vividly calls to mind the unparalleled one in our notes, Vol. II., under *Trephining*, of a long sharp chisel, implanted deep into and through the vertebral column, and which, by herculean efforts, was extracted on the spot, the proper course undoubtedly. T.]

### § III.—*Abdomen.*

Foreign bodies in the abdomen, like those of the thorax, arrive into this cavity sometimes directly from the exterior, sometimes after having passed through the mouth and œsophagus. A boy (Planque, *Bibl. de Méd.*, t. I., p. 46,) thirteen years of age, having swallowed an *ear of barley*, discharged it three weeks after, by an abscess which was formed in the left hypochondrium. The same accident was followed by the same result, in a little girl in Silesia, (*Journ. des Savants*, October, 1688.) When balls, lead or other projectiles strike the abdomen, they enter into the peritoneum, or are arrested in the thickness of the soft parts. In the last case, the foreign body should be extracted without hesitation, by the ordinary processes. Should the ball have dragged in with it in such manner as to have pushed ahead of it, and become wrapped up (*de manière à en rester coiffée*) at the bottom of the passage, in a portion of the clothes of the patient, nothing more would be required than to make action upon this last, in order to remove the whole. It is what I did successfully in two of the wounded in 1830, and each of whom had received a ball, one below and to the right of the umbilicus, and the other to the outside and left of the same point. Supposing, on the contrary, the projectile had fallen into the peritoneal cavity, and that there was no means of ascertaining precisely its exact situation, every attempt at extraction would be fruitless, and in fact extreme-

ly imprudent. It is difficult to conceive, therefore, how the contrary rule should have been reproduced in a recent treatise upon wounds from fire-arms, and that a surgeon should not hesitate to advise that the abdomen should be freely laid open, and that we should perform a sort of gastrotomy, to go in search of balls that have wandered among the convolutions of the intestines. Once in the belly, the ball may cause there various disorders. In a man who had received the discharge of a pistol, and whom I saw with Bogros, the ball had opened the hypogastric vessels, and speedily caused death. A similar fact has been published by M. Gibson. It is known that Carrel died of a wound of the intestines, and that the ball in him remained in the belly. Though in such a case we should even succeed in withdrawing the projectile, what would thereby be gained? It is the wounds it has caused, and not its presence, which is the source of the danger. Who, moreover, does not know, that balls, lead, and buck-shot, left in the midst of the tissues, become encysted, and frequently remain there a considerable length of time without materially disturbing the functions? Does not M. Larrey (*Clin. Chir.*, t. II., p. 521,) inform us that balls which had traversed the pelvis, rectum and bladder, have nevertheless not prevented the wounded from recovery? If the projectile was still in the tissues, we should even take care, while trying to extract it, that we do not cause it to fall into the belly or pelvis, as happened to that practitioner mentioned by Theden, (Thomassin, op. cit., p. 31.) As to foreign bodies that have arrived through the digestive passages, they have given rise to certain results, exceedingly curious. Legendre (*Biblioth. de Planque*, t. III., p. 560, in-4°,) speaks of an individual who, after a certain lapse of time, discharged per anum a *fork* which he had swallowed. Who is not familiar with the history given by Habicot, of the poor boy who, to protect them from robbers, decided upon swallowing his ten pistoles of gold, and who after being on the point of being suffocated, discharged them piece by piece, through the anus, during the space of fifteen days? A curious history of this kind is that of Pierre Yvens, related in the Journal of Blégné (*Nouv. Découv.*, Mai, 1679, p. 188; et *Bibl. de Planque*, t. I., p. 51.) This man, who was an extravagant character, swallowed the steel (affilior) of a hog-killer, and retained it thus during five or six months. Not until then did an abscess form in the right hypochondrium, and allow the unfortunate porker to recover his instrument, which he had believed lost forever. Some time after, this foolish sort of fellow swallowed in the same way the leg of a porridge-pot, which he voided by an abscess in the left hypochondrium. Attaching no importance to these abscesses, Pierre Yvens took it in his head also to swallow a pocket-knife with its handle, (gaîne,) which at a subsequent period came out above and by the side of the lumbar vertebræ. A. Paré also relates (*Traité des Monstres*, liv. 25, chap. 16, p. 772,) upon the authority of Cabrolle, the history of a shepherd who was compelled by some robbers to swallow a *knife* half a foot long, and which remained in his body during the space of six months. An abscess having formed below the groin, allowed of this foreign body being extracted from it. Besides the other analogous facts related by Paré, there is also mention made of the operation of gastrotomy per-

formed upon A. Grunheide, (*Bibl. de Planque*, t. I., p. 51,) for the purpose of extracting a knife which had entered his stomach through the mouth.

Quite a great number of cases of gastrotomy to remove a knife directly from the stomach, have now been related. M. Larrey (*Clin. Chir.*, t. II., p. 269–369) says that Grager had recourse to this operation in 1613, and that Frisac also at Toul employed it with success. Beckher (*Arch. Gén. de Méd.*, t. XV., p. 274,) who, in the seventeenth century, makes mention of a similar operation and Bernes, or Barnes (*Ibid.*) who, according to M. Marion (*Thès*, No. 294, Paris, 1831,) had occasion for it,—do they refer to the same fact, or did each one have a case of gastrotomy? What prevents our rejecting such examples as manifestly apocryphal, is the fact that they are occasionally, in our own time, recurring in such a way as to dispel every kind of doubt. Caiyroche (*Bull. de la Fac. de Méd.*, t. VI., p. 451) gives a case of gastrotomy successfully performed upon a lady, who, for a long time previous, had had a fork in her stomach, and Valentin (*Ibid.*, 1807) relates a similar case of a silver spoon. At Paris, in fact, A. Dubois (*Ibid.*, t. VI., p. 517) was seen to take from an abscess in the iliac fossa, the blade of a knife which the patient had swallowed a long time previous. A misanthrope made an attempt upon his life and did not succeed; he then swallowed a tea-spoon. Nine months after, a tumor, which suppurated, appeared at the epigastrium. M. Otto (*Bull. de Therapeut.*, t. XV., p. 320) perceived it, and through this exit removed the foreign body, which was yet but little changed. The cure took place rapidly. [See notes under Special Operations, *infra*. T.]

[Instances of a similar character of swallowing jackknives, table and pocket-knives, bits of broken wine-glasses and tumblers, which had been first chewed up in the mouth; also of brass buttons, &c., have been very frequent in the United States for the last half century. These feats have been usually performed by reckless and intemperate persons, in high as well as low life, on banters, bets, &c. In some cases they have proved fatal, in others they have passed off, per anum, harmlessly, or after having caused considerable visceral disturbance. The jugglers of Hindostan, some of whom have exhibited in America, fearlessly insert, and that several times daily, a smooth narrow sword of one to two feet in length and near an inch broad, through the mouth and œsophagus, as far down as to the pyloric orifice, without the slightest injury to the parts. T.]

#### § IV.—*The Urinary Passages.*

The emigrations of foreign bodies, which have been introduced through the digestive passages, have at every epoch attracted the attention of observers. A woman, tormented with attacks of colic, was not cured, according to Van der Wiel, until after she had discharged through the urinary passages a ball she had swallowed. Among the examples of calculi of the bladder, which have exhibited for their nucleus, a pin, needle, point of a spindle, ear of wheat, ball, &c., it is probable that many of these reached there by this emigrating process. These substances having arrived in the stomach or intestines, get entangled in some of the folds of the mucous mem-

brane, and gradually escaping outside of them, continue to march in this or that direction, according to the disposition of the parts. Pins, needles, and very slender bodies, may in this way course to long distances without giving rise to symptoms of inflammation. Thus an infinity of cases are related where needles, which had previously been swallowed, had finally made their appearance under the skin. Should such bodies, in traversing through the cellular partitions and layers, ultimately reach the bladder, they might, as will be readily conceived, become there the nucleus of a calculus. Might it not be possible, also, that in becoming arrested in the ureter, after having pierced through the intestine, they would descend without difficulty into the reservoir of the urine? And could we not, in this manner, explain how worms, nuts, kernels of fruit, and beans, have been expelled through the urine? In the case of the soldier, mentioned in the *Journal of France*, (*Bibl. de Planque*, t. I., p. 48,) and who had a pin in the ureter; would he not, at a later period, have been affected with a calculus? A man about 30 years of age came into the Hospital of La Pitié, for a considerable contraction of the rectum. At the opening of the dead body we found in the pelvis a sub-peritoneal induration, which almost completely closed the rectum. A purulent passage extended beyond this as far nearly as the liver. A calculus of the dimensions of an inch, with a pin for its nucleus, was found between the ureter and ascending colon, at two inches below the kidney. The pin was situated in such way that its head still projected into the intestine, while its point was directed into the ureter. Is not this one of the cases, where nature leaves herself in some sort, to be guided by the state of the circumstances (*prendre sur le fait*)? Does not all this show, that but for the lithic concretion, the pin, escaped from the intestine, would have ultimately descended into the bladder.

#### § V.—Operation.

It is unnecessary to remark, that the presence of such foreign bodies does not in itself call for any surgical operation, so long as they do not, by any special manifestation, show themselves externally. When, therefore, they have been swallowed, we must confine ourselves to the conservative treatment of the organism, and wait until they make their way out themselves, or indicate their presence upon the exterior of the body by some particular symptoms. Under these circumstances, whether an abscess is established, or by the touch we distinguish the projection of the foreign body, we must no longer hesitate, but extract it as soon as possible. The rules to follow in such instances are subordinate to the particular circumstances of each case. Thus, should there be an abscess, it is to be opened freely, in order to give exit to the pus, after which, by means of a forceps, we seize hold of the foreign body to be extracted, and take it away with caution. Should the skin be sound, we first incise it to the proper extent, after which, the foreign body having been secured, we should proceed to the required dilatation and enlargement of the track which is to serve for its passage. As the outer surface of the stomach or of the intestines will almost necessarily have contracted adhesions with the corresponding portion of the

abdominal wall, we may enlarge the perforation of these organs without necessarily opening into the peritoneal cavity. Nevertheless, these adhesions being sometimes irregular or very circumscribed, there would be danger in enlarging too liberally in one direction, and an indication presented of having recourse to multiplied incisions. It is, moreover, a remarkable fact, that after these operations the wounds generally close up quite rapidly, even after the digestive cavities have been largely laid open. Experience having established that the cure is not so prompt and certain where ulceration exists as where the organs are merely divided, it is evidently much better to operate in good season than to wait for the tedious processes of nature.

## ARTICLE II.—THE LIMBS.

Foreign bodies when introduced into the limbs, are more easily recognized than in the splanchnic cavities. They act, however, nearly in the same manner, except that they do not travel there by the intervention of the natural canals. It is easy to conceive, however, that small grains of lead or other bodies of small size, might possibly after entering a vein be transported to the heart, and give rise to the suspicion of a lesion of an entirely different nature. This fact, indeed, might involve legal consequences sufficiently serious to justify the mention I have made of it. An inhabitant of Vannes having been engaged in a duel, received the discharge of a pistol in his neck. Repeated hemorrhage and various accidents took place, and death followed on the sixteenth day. The opening of the dead body demonstrated that the carotid artery had been opened, that the ball had entered into the jugular vein where it still remained, that it had formed here a varicose aneurism, and that but for a slight contraction in the vein, the projectile would evidently have fallen into the heart. I have seen the specimen and can guarantee that all that has been said in relation to this case by M. Jorret is perfectly correct. Surgery however could have nothing to do with the extraction of such bodies, unless they had become introduced into the superficial vessels. As to foreign bodies resulting from mortification and necrosis of the bones or soft parts, I have treated of them at sufficient length under the chapter on exsections, to make it unnecessary to recur to them now. There remain then the foreign bodies which have come directly from without, and those which may have come from a distance through the cellular tracks, (*traînées*.)

### § I.

Under these we have *needles* and *pins*. A pin having a head, does not generally go deeper than the level of the skin, and may be extracted without difficulty in almost all cases. It is no longer the same with pins without heads and with needles. Frequently we see these lost in the tissues, while they allow the wound by which they entered to be cicatrized, and cannot be found again without difficulty. A young man sat down upon the point of a needle and pricked himself severely; his master being alarmed, sent for me two hours after. Finding neither a puncture nor the slightest ap-

pearance of a foreign body on the point of the breech indicated by the patient, I supposed he had been deceived, and that the needle had been lost in the chamber. At the expiration of eight days, something sharp-pointed was perceived underneath the skin upon the outer side of the thigh, and which I laid bare with a cut of the lancet; it was the point of the needle, which then became easy of extraction. A boy eight years of age broke a needle in his calf. He himself insisted that there was nothing left in the leg; his mother, on the contrary, was convinced that every thing except the eye of the needle had become hidden in the flesh of her child. By dint of searching, I was enabled to discover at the distance of two inches from the puncture a hard point, pressure made upon which caused pain. Having laid open the skin at this place, I found the needle there lying naked, and that it was an inch in length. It would be difficult for me to say how many times the same thing has happened to me in respect to the fingers, palms of the hand, fore-arm, arm, shoulder, foot, body of the leg, thigh and breech. Even the face and cranium are not exempt from similar occurrences. When we are called therefore to such wounds, two cases may present themselves: either by means of a well-conducted exploration we establish the presence of the foreign body in the tissues, and then it is important to extract it forthwith; or in spite of our most minute researches we find or recognize nothing, and here prudence suggests that we should wait and watch the wound, and that we should be prepared for any event, without affirming that there is nothing there, but also without having recourse to any expedient or any inconsiderate operation. [See notes on Special Operations, inf. T.]

## § II.

After needles, fragments of glass are those which, having been introduced under the skin, most frequently remain there without producing inflammatory symptoms, while at the same time allowing the external wound to close over them. An adult man retained for the space of fifteen months, under the integuments of the forehead above the eyebrow, a triangular plate of glass nineteen lines in length and eight lines in width at its base. For a long time concealed by a cicatrix, this foreign body ultimately showed itself externally and projected at two or three lines above the eye, but without ever having produced the least degree of inflammation, or any other result than a slight degree of inconvenience in the movements of the eyebrow and forehead. After having moderately enlarged the wound, I extracted the body, which proved to be a fragment of a pane of glass. In the thigh I have seen fragments infinitely larger. A laborer, aged 25 years, was thrown from the basement story through a window, and by this means received a wound in the left thigh, for which he was taken to the hospital of La Pitié. I found the wound an inch and a half long, and upon the outer side and near the middle of the limb. I removed from it three pieces of glass, respectively of an inch, half an inch, and some lines in length. Every thing went on well until the eighteenth day, when, in pressing slightly upon the thigh of the patient, I perceived that he felt, in the neighborhood of the femoral vessels, a considerable deal

of pain, which was augmented on the least movement of the muscles. An incision there enabled me to extract from it a portion of glass *five inches* in length by about fifteen lines in breadth, together with some other small fragments of the same substance. Some dilations afterwards became necessary, and the patient recovered. Another young man had retained in this way, for the space of seventeen days, an irregular portion of glass of an inch in diameter, and without experiencing any other inconvenience than some pricking when he was obliged to walk. The wound being cicatrized, I made an incision of two inches externally, and where this fragment had arrived, and this slight operation was followed by nothing unpleasant. The palmar surface of the fingers and the plantar surface of the foot, are frequently the seat of similar wounds. I have removed a fragment of glass more than an inch long, and three lines in breadth, which had existed in the fold of the arm for the space of seven months. A young distiller who had broken a liquor phial in his hand fifteen months before, though cured of his wounds, had never ceased to be entirely without pain. An incision of an inch in length upon the point originally wounded, enabled me, after some researches, to reach and extract a triangular fragment of glass of from five to six lines in length. I was obliged to perform the same operation, occurring from a similar accident, on a young chemist then employed at the hospital of La Pitié.

A man had, for the space of thirteen months, at the root of the thenar eminence, an imperfect cicatrix resulting from a wound caused by a piece of broken bottle. As this man scarcely suffered any and did not mistrust that any thing remained in the hand, he continued at his labors, only occasionally asking some surgical advice of the surgeons of the three or four towns where he had been. Suspecting that there was some foreign body there, I made an incision in the track of the ancient wound. The probe having confirmed me in my first idea, I enlarged the incision and succeeded in extracting a fragment of glass fourteen lines in length by two in diameter in its smallest dimensions. To explain how fragments of glass, though angular, irregular and cutting in their edges, should thus be enabled to remain in so many instances in the midst of the living tissues, without producing any reaction, is a matter of very great difficulty. All that we can say is that they are insusceptible of chemical action, or enlargement or diminution, and that being devoid of inequalities, (*rugosités*,) the glass is restricted in its action to the mechanical or physical disturbance of the parts, without irritating them or altering them in any manner whatever. As for the rest, whether it admits of explanation or not, the fact is nevertheless as stated, and as experience has a thousand times demonstrated, which makes it proper that it should be so received in practical surgery.

### § III.

Glass, moreover, is not the only substance which sometimes acts in this way in the midst of the organs. I have seen in the midst of delicate tissues large sized and long pieces of *wood*, which caused no more disturbance than bits of glass. An adult man had been

wounded in breaking a box of black wood eighteen months before. The wound, which was between the thumb and forefinger of the left hand, soon healed. Nevertheless it reopened from time to time, and the patient suffered a little at the thenar eminence. I removed from it a piece of wood of eleven lines in length and two lines in its other diameters, resembling a nail or peg, and which had been driven in from before backwards, from the commissure of the thumb to the root of the first bone of the metacarpus, between the muscles in that region. A man employed in the service of Count Demidoff, came to the hospital of La Charité, in consequence, he said, of an abrasion which he had received from the point of a nail in breaking open the cover of a box.

The injury had occurred fifteen days before, and there was no longer any wound; but a phlegmonous erysipelas had appeared upon the fingers and almost the entire hand. Having made some incisions to give greater freedom for the escape of the pus, the parts were speedily disgorged, and the patient believed that he would soon recover. Having returned to his labors the inflammation reappeared, and he came back to the hospital at the expiration of a month and a half. Finding a spot on the anterior surface of the metacarpal bone of the middle finger more sensitive than the others, I made there a deep incision. Surprised to find the point of my bistoury arrested as if it had struck into wood, I examined the bottom of the wound, and found there a foreign body, which I immediately extracted with a strong artery forceps. What was not our astonishment in finding that this was a pliant fragment of wood fifteen lines in length! This patient, who had still some other particles of wood remaining in the hand, was ultimately cured of his wounds and inflammation; but the adhesion which took place among the different tissues and the tendons, and especially their synovial sheaths, left a stiffness and numbness in the fingers, which he will probably never get rid of. Bagieu (*Examen de plus part. de la Chir.*, etc., p. 103,) speaks of a splinter of wood 26 lines long and 8 in breadth, which had remained for two years underneath the skin below and outside of the knee, without any body having ever suspected it. A dragoon treated by Thomassin, (*Extract. des corps étrang.*, &c., p. 10,) had for the space of three weeks, without knowing it, a piece of wood in the skin 24 lines long. In the year 1838, I saw at the hospital of La Charité a man who had under the skin upon his legs a great number of indolent tubercles, which had been there twenty-five years, and which had been produced there in consequence of the explosion of a mine. Desirous of ascertaining if they were in reality foreign substances, I removed one of them which had caused considerable pain, and which was of the size of a small nut, and was situated above the internal malleolus of the left leg. This foreign body I found to be an irregular fragment of iron, which had become incorporated (*combiné*) as it were with the surrounding cellular tissue. A few days later, having removed a second fragment, I found that this was a portion of brownish earth, dried very hard, and also combined with the living tissues; while other portions were of the melted metal (*la fonte*) or silex. Quite a long fragment of bone driven in by the powder, was also found in the tissues.

§ IV.—*Balls,*

More perhaps than any other foreign body, may form for themselves a lodgment, and thus establish themselves in the living organs, and remain there for an indefinite period of time, without the patient's being aware of it. There are in fact some cases of this kind, where they are found at a great distance from their place of entrance. In the case of the Prince of Rohan they had ascended along the course of the tibia, and in that of Saint Mars (Dionis, *Operat.*, p. 818,) along the femur; in a child which recovered, two balls which had entered at the thigh ascended as high up as into the belly, (Blégny, *Jour. de Méd.*, t. IV., p. 78.) M. Dujaric Lasserre (*Cas de Chir.*, etc., p. 23, 1830,) in extirpating a tumor which a patient had had for a long time upon the sternum, was greatly astonished to find two balls in its centre. In the bones balls have often been found which had remained there from ten to fifteen and twenty years, without giving rise to any particular symptom. An ancient soldier who, in consequence of a gun-shot wound received twenty-five years before, had a necrosis at the lower third of the femur, with an ulcer, which from that date had opened and closed a great number of times, ultimately died of pulmonary phthisis at the hospital of La Charité in 1836. The examination of the limb in the dead body of this patient, enabled us to ascertain that he had a ball in his ham, which had worked itself a perfectly smooth and regular cavity upon the posterior border of the articular interstice. It has been laid down, therefore, as a precept from these facts, to make no dilatation (*débridement*) or any serious operation whatever, for the purpose of discovering either balls, shot, or any other foreign body whatever, so long as we have not ascertained to a degree amounting almost to certainty, the place where they have been arrested. When, however, we have ascertained in addition, that they are retained in the midst of the tissues, we may proceed in opposition to this precept, if there is no important organ that might be wounded, or if the operations deemed necessary, should in themselves present no difficulty or danger. A fragment from a grenade, as large as the hand, was extracted from the breech of an officer by Dionis, (*Op.*, D. X., p. 812.) Ravaton (*Chir. d'Armée*, p. 210,) and Bagieu (*Examen*, &c., p. 78,) have removed biscayans of from nine to twelve ounces in weight, and which had remained a long time in the tissues, causing there all sorts of disturbance. A ball imbedded in the instep, at the bottom of an abscess, was left there at the desire of the patient, and did not, it is true, prevent the wound from consolidating; but a fistula in the thigh did not close up until after Deschamps (Thomassin, p. 28,) had effected the extraction of a ball which rested upon the femur; a ball which had passed through the knee, and which was left in the ham, made it necessary to amputate, and caused the death of the patient, (*Journ. de Méd. Milit.*, t. XIV., p. 535.) Another ball on the contrary, retained between the patella and femur, after having traversed the knee from behind forwards, was extracted with entire success by Desport, (*Plaies d'Armes à feu*, p. 242.) Morand (*Opusc. de Chir.*, 2e partie, p. 252,) and Thomassin (*op. cit.*, p. 100,) have obtained similar successes in making use of the seton.

## ARTICLE III.—OPERATIVE PROCESS.

Operations required for the extraction of foreign bodies must necessarily vary from an infinity of circumstances. In most cases, the fingers, the dressing or the artery forceps, or the end of a spatula, or extremity of a probe, or the polypus forceps properly managed, will answer the purpose. But it is proper to add, that in certain cases we require instruments and operations that are more complicated.

§ I.—*Foreign Bodies retained in the Skin.*

It is rare to find any other matters implanted in the dermis except grains of powder, small shot, sand, pieces of earth or mortar. Supposing that it should be desirable to extract them, we should proceed best in doing so with the point of a pin, an ordinary needle, or a lancet, or cataract needle. It would be then necessary to scrape carefully, and as perfectly as possible, each little cup or spot on the skin with the instrument, if we desire to prevent all subsequent abnormal discoloration.

## § II.

Rugose or irregular bodies concealed underneath the skin or in the depths of the parts, require that we should first lay them bare by means of incisions of sufficient length. After that, it is advisable to seize hold of them with an erigne the same as for a tumor, and to remove by excision the cellular tissue, which it seems in most instances has become incorporated with them. Pieces of wood, scales of bone, portions of clothing, and inert concretions that have come from without, especially belong to this category. Fragments of glass, pins, needles, and all metallic bodies somewhat regular in shape, also require for their extraction an enlargement of the wound by which they entered, or that we should cut down to them in a proper manner by new incisions. As they contract no adhesions with the natural tissues, these foreign bodies should then be seized and extracted either by means of the fingers or the forceps. Being also sometimes very brittle, they moreover exact that the tractions made upon them should be managed skilfully and prudently.

## § III.

The enumeration which I have made farther back, shows that certain foreign bodies partially show themselves outside in the form of stems or plates. Thus a needle, pin, splinter of wood, or fragment of glass, the blade of a knife or sword, or a foil or ramrod, may be plunged to a greater or less depth into the tissues, while at the same projecting outside to the extent of some lines or inches. In such cases, the hand or fingers are the first instruments to be had recourse to, and they almost always suffice when the foreign body has traversed only the soft parts, and offers a sufficient purchase outside. Next to the fingers come the dressing or the artery forceps, and

lastly the blacksmith's nippers. [See under *Trephining*, Vol. II., the fortunate application of this last power in the case I have above alluded to. T.] If the foreign body has been implanted in bone, it is possible that the tractions made in this way may not be sufficient. It is in such cases that the nippers called *tricoises* in veterinary surgery, may become of great utility. Seizing the projecting portion of the foreign body, near the tissues, in the manner of a cutting pliers and without incurring the risk of too readily breaking it, they furnish the operator with an extreme degree of force. If a solid plate of wood or metal were placed on the skin around the projecting stem, the nippers would thus be furnished with a point d'appui, by which we would be enabled to succeed with them much better, and without causing so much concussion upon the organs of the patient. If by chance the surrounding body should project into some natural cavity, as in the pleura, as was seen in the case of Gérard, or the mouth, nose, vagina or rectum, it might be advantageous while making traction outside, to apply on its point a finger, armed with a thimble, so as to push it forward at the same time. This is what Gérard states that he did, and what M. Champion has also sometimes had recourse to, with the precaution of placing upon his thumb only a few transverse grooves. It is readily perceived, however, that for the mouth, vagina and rectum, the cavity of a small scoop, or small spoon, would answer full as well, and be more convenient than a thimble. The instrument of M. Charrière would become important and should be preferred where the resistance to be overcome appeared to be very considerable, and where it would be requisite to avoid all concussion in withdrawing the blade or metallic rod which had passed through the bones.

#### § IV.

Another circumstance still may present itself; it is when the foreign body implanted in the bones does not furnish a purchase either without or within the part. Then it becomes necessary to apply the *trephine* by embracing the projectile in the crown of the instrument, or we may employ the chisel, gouge, and mallet, in order to chip out at the same time the portions of bone which confine it, or at least to liberate its periphery, and enable us to seize hold of it with some kind of instrument. If the bone were not large or important, it might then be allowable to divide it on the two sides of the wound, and exsect it entire by means of any description of osteotome.

#### § V.—*Ball*.

No foreign body, in relation to the means to be employed for their extraction, has more particularly occupied the attention of surgeons, than balls. Every body knows the species of forceps called the *ball-extractor* (*tire-balle*) of *Alphonse Ferri*, and from whence have been derived almost all the litholabes of our days. The spoon-bill, the elevator, formerly so much used, and the tribulcon devised by Percy, have been introduced into surgery almost exclusively for this purpose; but the noose, (anserine,) concave and toothed forceps, the crow's-beak of Maggi, the cane-beak and stork's-bill, the instru-

ment of Ravaton, a mere improvement of that of Alphonse, the sheath-forceps of J. L. Petit, erroneously called Hunter's forceps, (Thomassin, p. 55,) the lizard's-beak, parrot-billed and claw-forceps, and the auger-forceps (tarières) mentioned by Guy de Chauliac, Paré and Fabricius ab Aquapendente, the crotchet, and an infinity of other instruments, which are figured or described in the authors I have named, are generally abandoned at the present time. We still find in Thomassin, (*Extract. des corps étrang.*, Strasbourg, 1788, pl. 1, fig. 3, 4, 5, 6, 7, 8,) the figures of three descriptions of forceps, of which one only, viz. that of the figure G, deserves to be retained. This is an instrument analogous to that of Ravaton, composed of two pieces, which are intended to glide upon each other in the manner of the pelvimeter. When opened it represents a lithotomy scoop. An effort is made to introduce it below the ball, which is then secured by forcing against it the other half of the instrument, which is straight and slightly pointed. It is rare, however, that extraction of balls cannot be effected by means of ordinary instruments or the polypus forceps. To favor the operation it is unnecessary to replace the patient in the position he had at the time of receiving the injury, unless the foreign body should appear to be less easily accessible by any other mode. Most usually it is advantageous to enlarge the opening by which the ball has entered, and consequently to make some incisions. If there should be but one opening, this is the one to be dilated. If, however, the ball should be found at a great distance, and that in order to fall directly upon it, it would only be necessary to divide a few layers that were neither very thick or important, we should not meddle with the first wound, but proceed to make a counter-opening. When once laid bare, we endeavor to force it out by enucleation, or by means of the finger, or a spatula, scoop, or spoon-bill. Supposing it should have existed a long time in the tissues, and had become enveloped in them, it would be better to remove its cyst with it than attempt to disengage it from that. I have stated, in speaking of balls introduced between the ribs, how we should, under such circumstances, proceed in removing them. It is scarcely but for balls that have become actually encrusted or imprisoned in the body of bones, that there can be a call for the trephine, or for some of the forms of exsection. Thus in the cranium, os calcis, olecranon, body of the tibia, condyles of the femur, and great trochanter, the extraction of the ball might require the division of the bone itself, and consequently become the occasion for the use of the trephine or for exsection. The most simple mode then is to include the ball within the crown of the trephine, so as to remove it with the osseous disc. If this process were not applicable, it would be necessary to apply the instrument to the neighborhood of the ball, in order that a chisel inserted in the hole might reach underneath the foreign body, and thus cause its expulsion. It is readily understood that by means of the chisel, gouge and mallet, we should succeed equally well in bones of a certain size, those of the limbs, for example, but that there would be some danger in making use of those instruments to the cranium. If the trephine should not appear to be very suitable, it would still be practicable to have recourse to the concave rowels of M. Martin, or the osteotome of M. Heine or M. Charrière, after

the rules laid down in the chapter on *Exsections*. It is moreover well understood, that during these operations we ought, by all the means known, put ourselves on our guard against wounding the vessels, nerves, tendons, articulations, and in fact all the important organs; and that, whether at the moment of the operation or afterwards, we should prepare ourselves against every kind of danger or accident that might occur, the same as we would for any other operation of a somewhat serious character.

#### ARTICLE IV.—FOREIGN BODIES IN THE ARTICULATIONS.

Among the foreign bodies which become established in the centre itself of the organs, I design to say one word only of those of the articulations. It is not of fragments of fungosities, fractured bones, diseased cartilages, or particles detached from the neighboring surfaces and become free in the joint, in consequence of a malady still existing, that I wish to speak upon the present occasion, but of those bodies known under the name of *free cartilages*, [loose] in the articulations; bodies of which I have pointed out the origin, symptoms and danger in another work; (*Dict. des Sc. Méd.*, 2e edit., t. IV., p. 179.) It is in the ginglymoid articulations that they have been most frequently encountered. Morgagni, according to Boyer, had seen many of them in the tibio-tarsal articulation. Haller states that he found *twenty* in the temporo-maxillary articulation. An elbow examined by M. Robert, contained eighteen or twenty; and M. Malgaigne states that he found nearly *sixty* in another humero-cubital articulation. It is in the knee, nevertheless, that they are almost exclusively found. Paré, Pechlin, Henkel, Simson, Hewitt, Ford, Bromfield, Thédén and Desault are the authors who have more particularly drawn public attention to this subject. The size of these bodies is exceedingly variable. The one mentioned in the case of Pechlin was of the size of the finger, while that in the patient of Paré had the volume of an almond. I saw one removed from the knee, in 1822, which might have been taken for a flattened chestnut, [meaning the *marron* or large chestnuts of France, which are treble the size of our American chestnut. T.] A man admitted into the hospital of Saint Antoine in 1829, had one which was yet larger than that by one half. Sometimes, however, they scarcely exceed the size of a barley seed. When there is but one only, it is generally of large size; when numerous, on the contrary, they are almost always diminutive. Some are hard and, as it were, stony; others bear so strong a resemblance to fragments of cartilage that it is difficult at first to distinguish them from this last. M. Bourse, a physician in the environs of Paris, sent me one in 1834 for the Royal Academy of Medicine, which, to all appearance, was only a fragment of the external condyle of the tibia still invested with its cartilage. They have ordinarily less consistence, and may almost always be crushed under a certain degree of pressure. They contain neither vessels nor laminæ, and present no appearance of texture. Whether loose or not they have an unctuous aspect, which has made some suppose they had a synovial envelope. Their centre is usually the part that has least consistence, and desiccation considerably dimin-

ishes their dimensions. Being truly foreign bodies they are, in my opinion, simple concretions, whether fibrinous or lymphatic, or morbid sanguineous productions. These cartilages when they have once become smooth and unctuous, do not seem to be of a nature to disappear spontaneously. We can conceive only that they may become attached, engrafted or concealed in some region or some recess of the articulation, where they are sheltered from every kind of pressure and displacement for the future. It is thus that certain patients, after having been more or less tormented by them, have suffered no more and believed themselves cured. Other persons, again, are so little incommoded by them, that they scarcely think of them. A young lady of Arras, who consulted me in 1832, had had one in the knee for ten years, and suffered only when through accident she hit it against some other body. I saw in 1830, at the hospital of Saint Antoine, a man of from fifty to sixty years of age who had never been troubled by one that he had had in the knee for more than twenty years. But the great majority of patients unfortunately have not the same good luck. Besides the pain that the least unsteady movement may re-excite, they have, moreover, to fear in the sequel that the joint may become altered, as in the patient of M. Knox, or that it may become attacked by either acute or chronic inflammation; whence comes the necessity of considering the operations that possess the power of effecting a cure. Various means have been proposed for this purpose. Extirpation is the first which has presented itself to the minds of practitioners; but experience having soon demonstrated its dangers, it has been necessary to devise others. Compression in fact is the only resource that can be advantageously substituted for it in certain cases. Whether by fixing the body at a determinate point external to the articulating surfaces, it places it out of the possibility of being injured, or whether it acts by promoting its solution and absorption, certain it is that many patients have experienced great relief from it. Middleton obtained undoubted successes from it. Gooch also says he has had much reason to be satisfied with it. The same is remarked by Hey, who gives many examples, and who made use of a laced knee-cap (*genouillère*). Boyer in two or three cases was equally fortunate. When we have decided upon making use of it, it is important above all, to compel the cartilage to recede into a pouch (*cul de sac*) of the capsule, on the sides of or above the patella, for example, if it is in the knee, in order that by fixing it there we may maintain it there firmly, without having need of any very great degree of constriction. The bandage or knee-cap, moreover, should be disposed in such manner, that the patient may not be impeded in walking. We would not have recourse to absolute rest, nor an apparatus for preventing any movement in the joint, unless the first method had been used for a long time and failed. Its use, moreover, is very inconvenient; the more so inasmuch as it acts at first only as a palliative, and that it is often necessary to continue it for a number of years before a radical cure is effected. Also, it frequently fails entirely. Raymarus had seen its inefficacy in the hospitals of London.

M. Averill has given the case of a patient in whom M. Ballingall

had used it without any advantage, and a great number of practitioners have related similar failures. Their extraction is an operation so simple and easy in appearance, and so prompt, that it seems astonishing at first that compression should be preferred to it; but the surprise ceases the moment we reflect that it exposes to the same dangers as wounds penetrating into the articulations. A patient operated upon by Hewitt, and whose case is given by Raymarus, died in consequence of it. That of Simpson created the greatest degree of anxiety for several months. M. S. Cooper cites two other cases that perished from this cause. An example also is given in the cases of M. Kirby, which is calculated to inspire serious apprehensions. A young girl, whom I saw operated upon in 1822, was seized with symptoms so formidable, that her recovery attended with an ankylosis seemed in some degree to be miraculous. M. Richerand states that out of twelve operated upon by him, four died; two mentioned by M. Decaisne (*Encyclogr. des Sc. Méd.—Bulletin Belge*, 1836, p. 102) also succumbed. Bell, on the strength of facts of this kind to which he had been witness, goes so far in such instances as to express a preference for amputation of the leg, unless the cartilage should appear to be very superficial. David, cited by M. Ledo, confines himself to an ankylosis which he recommends should be artificially produced. Bromfield, Cruikshank and Boyer express nearly the same apprehensions. It nevertheless appears to me that the danger of this operation has been exaggerated. Ford, Hunter and Desault have performed it sufficiently often without its being followed by any unpleasant results.

Numerous cases of a successful issue have been collected in the theses of M. Champigny and M. Ledo. M. Larrey, J. Clarck, M. J. Coley, M. Brodie, M. Allan, MM. Muller, Soender and a multitude of others have also furnished similar examples. Aumont (*Archiv. Gén. de Méd.*, t. II., pp. 412, 472,) removed four of these bodies at two different occasions, with an interval of forty days, without causing the least accident. Most frequently, in fact, the cure is exceedingly prompt; and many patients have had it in their power to walk and resume their usual occupations at the expiration of six or eight days. So great a difference in the results is however readily explained. If it is possible to obtain immediate reunion of the wound and no inflammation take place under it, the whole matter is reduced to one of the most simple solutions of continuity. On the contrary, as soon as inflammation attacks the synovial and the interior of the joint, there is every thing to apprehend, and the danger of the disease cannot be dissembled. We should not therefore operate until after having duly weighed all these different circumstances, and forewarned the patient or some of his friends of the risks to which he will be exposed. The following is the rule which prudence, in my opinion, prescribes in such cases. So long as the cartilage produces but slight inconvenience we should endeavor to persuade the patient to support it; if it really causes disturbance in the functions of the joint, compression is then indicated. When it does not yield to the bandaging, or that the dressings used cause too much inconvenience, it is then time to think of its extraction. We should not however decide upon this step when the cartilage is concealed deep

within the joint or too difficult to be reached from without, unless it shall have produced unpleasant accidents, and after having in vain made trial of the other means. In such cases then when the cartilage, on the other hand, is very much diseased, and that it may be easily fixed without the articular interline and near the skin, the operation has every prospect of success. Many surgeons apprehending the introduction of air into the capsule, have suggested that we cannot take too much precaution on this point. Also to prevent the parallelism of the wound of the synovial and that of the integuments, they have carefully endeavored to draw the skin sometimes upwards, after Bell, at other times downwards, according to Bromfield, and in some instances to the side, as recommended by Desault and Abernethy.

What I have said of the action of the air, in speaking of articular wounds, (*Dict. de Méd.*, art. *Articulation*—see also M. Velpeau's opinions and those of other surgeons on this matter in our abridged account of the *Discussion on Tenotomy*, at Paris, in our notes of Vol. I. of this work,) renders it unnecessary for me to discuss here the value of these precautions. The only precaution which really deserves to be retained, is that which consists in conducting the body to be extracted as far as possible from the centre of the articulation, and to a point where there is the least amount of important parts to be divided. Being once brought there, it is firmly held between two of the fingers, or better still, as recommended by M. Averill, by means of a metallic ring, so as to stretch the skin uniformly, as advised by Simson, Theden, Vielle, &c., and in order that it may not escape under the action of the instrument and re-enter the capsule we have just opened. As for the rest, the most rapid and neat incision is evidently the best. For example, it is advisable to make it fall perpendicularly upon the foreign body, and to give to it at once an extent proportioned to the size of the morbid concretion. If the cartilage does not emerge by pressure in the manner of a kernel out of its fruit, we immediately seize it with a forceps, hook or erigne, and with one cut of the scissors divide the pedicle if it has any. The wound being brought together with adhesive plaster, the most perfect repose is recommended up to the time of its complete cicatrization. We might also, for greater security, apply to the whole of the joint exact but moderate compression, and keep the dressings wet with cold water during four or five days. As the accidents, after all, which may supervene, belong to arthritis complicated with wounds, we have no need of occupying ourselves with them any further. I will only call to mind that the disease is very liable to return, and that we must take care not to pronounce too sanguinely on this point.

## TITLE FOURTH.

### SPECIAL OPERATIONS.

#### PART FIRST.

#### OPERATIONS WHICH ARE PERFORMED ON THE HEAD.

---

### CHAPTER I.

#### THE CRANIUM.

#### ARTICLE I.—FUNGIOUS TUMORS.

DEGENERESCENCES of the dura mater almost always exhibit themselves under the form of tumors. These tumors, united under the title of fungous tumors since the time of Louis, are nevertheless sufficiently varied in their nature; there have, moreover, been associated with them a certain number of bodies which are altogether independent of the dura mater. The case mentioned by Hébréard (*Bull. de la Fac.*, t. V.) was a species of cyst, filled with pultaceous matter, and lodged in the left middle lobe of the brain, and which had only subsequently invaded the dura mater. In the same way, also, certain cases related by Abernethy (*Surg. Obs.*, vol. II., p. 51, 54.) seem to belong to degenerations of the brain, rather than to those of the dura mater. The confusion in this respect is so great, that we find comprised under the same title, fibrous, scirrhus, and hematic tumors, encephaloid masses, and various vegetations and fungosities which project from underneath the integuments of the cranium, whether they have had their primitive seat in the dura mater, the substance of the bones, or in the brain itself.

#### § I.—*Fibrous Tumors.*

Though rarely found there, masses of a purely fibrous character are, nevertheless, sometimes encountered in the cranium. M. Senn (Espinosa, *Thèse*, No. 129, Paris, 1825) appears to have met with an example. In that which was exhibited to the Academy of Medicine in 1825, (*Archiv. Gén. de Méd.*, t. XIII., p. 121.) the tumor was of the size of an egg, occupied the base of the cranium posteriorly and to the right, had depressed the corresponding lobes of the brain, and had not been revealed by any symptom during life. As these tumors do not appear to have been yet seen except on the outer surface of the dura mater, it would have been interesting to know if the fibrous productions noticed by M. Del Greco (*Arch. Gén.*, t. XXIII., p. 432) in the pterygo-maxillary fissure, or the nasal fossæ,

and by M. Rayer in the zygomatic fossa, in a woman who died at La Charité, in December, 1834, might not be classed in this category.

## § II.—*Hematic Tumors.*

The blood which has been effused into the diploe, or between the dura mater and the bones, between the dura mater and brain, or into the most superficial layers of the brain itself, may undergo various kinds of degeneration, and assume the form of tumors that might be denominated hematic. Some facts related by Abernethy come to the support of this supposition. In the case of a man 40 years of age, who had been struck violently by a stone, and who had in consequence thereof a species of cerebral hernia, the tumor was found to be similar to coagulated blood. (Abernethy, *Op. cit.*, vol. II., p. 51.) The same author speaks of a carpenter who was trephined for a depression of the parietal bone, and who, on the twelfth day from the operation, had a sort of cerebral hernia, the tumor in which case also appeared to have been formed from blood extravasated into the substance of the brain. From these facts, Abernethy moreover concludes, that what has been described under the name of cerebral hernia, is sometimes formed by blood, and that it is the same with certain fungous tumors of the dura mater. A fungus developed in the head of the tibia, and which he also compares to coagulated blood, also what I have said of contusions, and what I have often since remarked, (*Thèse sur les Contusions*, 1833,) serve but to corroborate this view of the subject. We could thus explain the appearance of tumors, which it seems difficult to range under cancers, and whose origin in reality appears to be ascribable to some external violence.

## § III.—*Phlegmasian (phlegmasiques) vegetations.*

Wounds of the head, fractures of the cranium and trephining have been frequently followed by fungosities and vegetations upon the dura mater, in such a way that Louis especially was led to confound these productions with true fungus. When they have been preceded by a protracted suppuration, and that the surface which supports them has become exposed to the air, it is difficult to say in what such fungosities differ from those which are so frequently found at the bottom of external wounds. In other cases, on the contrary, they probably result from some extravasation of concretible lymph, or from fibrine, and sometimes also from sanguineous morbid layers which have ultimately become organized. I have elsewhere (*Plaies de Tête*, 1834) published some facts of this kind. Perhaps also, the following case which I find in Abernethy, (*Op. cit.*, p. 106,) belongs to the same description. A man from thirty to forty years of age was afflicted with violent pains in the head, in consequence of a *severe salivation*; he was trephined and *pus was found under the bones*, and the dura mater, which was greatly thickened, was covered with a *soft and reddish substance*.

## § IV.—*Fungus.*

All, or nearly all the other tumors of the dura mater are cancers.

Almost all those that have been described, were evidently composed of encephaloid matter. The one which Paré (liv. XII., chap. 23) mistook for an aneurism, was formed from the *brain*. The patient mentioned by Rey (*Acad. de Chir.*, t. V., p. 22) had at the same time, a cancer in the thigh, or the *femur vegetated* (carnifié.) In that of Philippe, (*ib.*, p. 36,) the bones of the cranium were also vegetated (carnifiés.) In a case cited by M. Chelius, (*Arch. Gén. de Méd.*, t. XXVIII., p. 422,) the substance of the tumor resembled *marrow*; and how is it possible not to recognize a cerebriiform fungus in the encephaloid (venteuse) tumor, described at such length by Lecat, (*Soc. de Santé de Lyon*, 1798, p. 31)? The production was also of an encephaloid character in the two lunatics, noticed by M. Blandin, (Espinosa, *Thèse*, No. 129, Paris. 1825,) also in the case mentioned by M. Deneux, (*ib.*, p. 9,) the child eight years of age, spoken of by M. Marjolin, (*Dict. de Méd.*, 1e edit., t. IX., p. 305,) and in the case referred to by M. Bouvier, (*Bibl. Méd.*, 1825; or Espinosa, *Op. cit.* p. 10.) The tumor removed by M. A. Bérard (*Gaz. Méd.*, 1833, p. 735) was also an encephaloid mass; and in the patient of Siebold, (*Journ. Compl.*, t. XXXIV., p. 304,) and who died under the operation, it was a cavernous substance. Schindler also says (*ib.* p. 325) that cerebroid matter was found in a tumor of this kind in an aged woman, and M. Ebermayer (*Arch. Gén. de Méd.*, t. XXII., p. 229) states the same thing of a young girl aged four years. I could say the same thing of a lady seventy-one years of age, whom I saw with M. Durand, and also of a case communicated to me by A. Lauth. M. Cruveilhier also, who describes and has given the figures, (*Anat. Path.*, 8e livr.) six cases of fungous tumors of the dura mater, speaks only of encephaloid tissue. Scirrhus tissue, however, may also form its base. A woman, whose case I published in 1825, had two tumors of this last description, which I showed at the time to the Professors of the Faculty of medicine, and which I have for a long time preserved in alcohol. Whether encephaloidal or scirrhus, these tumors nevertheless differ in a remarkable manner, in respect to the parts of the membrane upon which they are situated. Out of fifty-one examples where this location was given, I found thirteen in the parietal regions, eight in the temporal, seven in the frontal, seven in the orbito-nasal, seven in the occiput, five in the vertex, three on the petrous bone, and one in the substance of the falx of the brain. I have, in two cases, seen them protrude from the ear, and once through the pharynx. All ages are liable to it. The following is the proportion in this respect, which was found in forty cases: From birth to ten years, six cases; from twenty to thirty, seven; from thirty to forty, ten; from forty to fifty, nine; from fifty to sixty, five; and from sixty to eighty, three cases: from whence it follows, as had been remarked by Boyer, (*Malad. Chir.*, t. V., p. 186,) that they are, notwithstanding, more frequent between the ages of thirty and fifty years, than at any other period of life. As to the sexes, I notice that in forty-four cases, twenty-three were men and twenty-one women. The legitimate *fungi* of the cranium are in their nature incurable. Those tumors which seemed to be formed by effused blood, like those examples given by Camérarius and Abernethy, (Ebermayer, *Journ. Compl.*, t. XXXIV., p. 301,) those which result from

syphilitic disease, and whose character is not decidedly cancerous, may alone leave some hope of cure. The prognosis for all the others, as has been remarked by Delpech, ought to be the same as for cancers of the most serious description. Moreover, these tumors sometimes are exceedingly slow in their progress. The patient of M. Graefe (*Arch. Gén.*, t. XVIII., p. 421) suffered for *thirty-seven years* and then died. The child mentioned by Schindler in the same way, lived over *five years*, (*Journ. Compl.*, t. XXXIV., p. 320.) Death did not take place until at the expiration of forty-five years, in the woman whom Robin (Louis, p. 18) caused to be exhumated five years subsequently; not until after thirty years in one of the patients of Voisin; (Thibault, *Thèse*, No. 133, Paris, 1816;) after ten years in another, and after fifteen years in a case extracted from the English Journals. (*Journ. Gén.*, Avril, 1814.) Also, it is less by hemorrhages, destruction of the tissues or extension of the degenerescence, that these tumors cause death, than by cerebral accidents which ultimately supervene.

In at least twenty cases out of fifty these accidents have been brought about by attempts at operations. These accidents consist of convulsions, delirium, symptoms of compression of the brain in fine, or of inflammation of the meninges. Sometimes also, as I have seen in the case of a woman, they are reduced to symptoms of debility, soon followed by hebetude, afterwards partial or general, or incomplete or complete paralysis, and a continual desire for repose or even for sleep. This state may be maintained for many months, gradually becoming aggravated. The patients then ordinarily expire without spasms, and so to speak, imperceptibly. In this last case death almost always happens by compression. Upon the opening of the dead body it is seen that the tumor has augmented in growth within, either in breadth or depth (*épaisseur*) so as to react with more or less degree of force upon the mass of the brain. If on the contrary the patients sink rapidly, we find the dura mater, or the surface of the brain inflamed and covered with pus, as though it were ulcerated or had undergone ramollissement, or been reduced to a state of putrilage (putrilage.) Small apoplectic cells (*épanchements apoplectiques*) are also sometimes remarked in the substance of the hemispheres themselves, and it is not unfrequent to find the purulent infiltration of the arachnoid extending itself as far as the occipital foramen and around the spinal marrow.

A. *Treatment*.—The disappearance of a fungus of the dura mater by resolution or suppuration has never been noticed; therefore, the plasters, pomades, unguents, and other topical applications proposed or made trial of, with a view of obtaining one or the other of these terminations, must be absolutely proscribed. Nor does the compression of the tumor appear to possess any more curative power; it is allowable only in the character of a palliative, and even then cannot be made use of but in a very small number of cases. The destruction of the fungus, whether by caustics, the ligature, or the knife, is in reality the only medication which merits consideration. Extirpation itself, the only remedy which reason sanctions the employment of, appears to have been but very rarely followed by success. In fact the external tumor is often only the smallest portion of the evil. After having removed it, we soon see it reproduced, if in fact new tu-

mors do not also appear. In this respect they have that feature in common with cancerous tumors in all other parts of the body. But not being enabled to make their way outwards, except through an osseous opening, it is not possible, as in the last, to designate their limits beforehand. I cannot perceive, however, why we should not attempt to extract them, when there is every reason to believe that they are clearly circumscribed, and that the disease is altogether local. In a woman who had been cured of cancer of the breast and who died of a pleurisy at the hospital of the School of Medicine in 1824, a scirrhus of the size of a small pullet's egg, commencing at the dura mater, had traversed the bottom of the right inferior occipital fossa, made a slight projection under the splenius muscle, and was found to be so regularly circumscribed, that it certainly would have been possible to have removed it entire, if its existence had been suspected during the life of the patient. The operation might be made trial of, at least for the fungous tumors of new-born infants, to which M. Nægelé has been one of the first to endeavor to draw the attention of practitioners, and also upon those which Abernethy derives from certain degenerated sanguineous or lymphatic concretions. Five out of the six cases in which caustics were employed perished. The individual mentioned by Cattier, (*Obs. de Méd.*, p. 48, obs. 15,) and who was treated by caustics against the advice of Pimpernelle, who advised the trephine, also died; it is also probable that that of M. Eck, (Ebermayer, *Jour. Compl.*, t. XXXIV., p. 323,) the only one which was cured, had only a simple hematic tumor. It is equally doubtful if M. Ficker, (*Ib.*, p. 320,) had to do with cancer, in the case of partial success, which he relates, with the ligature. As to extirpation, it has not, up to the present time, produced but very uncertain results. Franco says, (*Tr. des Hernies*, p. 485, An 1561,) "I saw a child who had a fungus tumor which two of us wished to extract, (tirer.) Nevertheless I was somewhat deterred, [je fus aucunement refrody—ancient French, T.] perceiving that the cure appeared to be difficult and not what it seemed to be (non tant qu'elle l'estoit); at the expiration of some days, my companion alone undertook it, when he found it within the brain itself, which was followed by the death of the patient. It is therefore very necessary to reflect and to ascertain (taster) if the brain is or is not entire." A patient mentioned by Camérarius (*Ephém.*, c. n. dec. 2, obs. 99, an. 8) also died from this cause. Amatus, (Cent. 5, obs. 8,) Schmucker (*Bibl. Chir. du Nord*, p. 10,) and Rossi, (*Méd. Op.*, t. II., p. 261,) relate similar instances. It is necessary also to concede that it has scarcely ever been successful. In one of the cases of M. Walther, (tom. XXXIV, p. 314,) he was prevented from finishing the operation by a hemorrhage which made it necessary to apply the ligature to ten arteries; in a case mentioned by Klein, puncture was had recourse to, and then an incision. M. Ebermayer, (*Archiv. Gén. de Méd.*, t. XXII., p. 229,) in the case of a child of four years, whose history he gives, mentions only a single cut of the lancet. Nor was there any other treatment than incisions made use of in the patient of Sivert, who nevertheless died two days after.

In the case of Rey, (Louis, p. 22,) the tumor was only laid bare without removing it. The patient of Courtavoz and Chopart, (*Mém. de l'Acad.*, t. V., p. 28,) died on the following day, though here

also incisions only were made use of. A similar attempt was followed by the same results in the case of Philippe, (*Ibid.*, p. 36.) Nor was the excision complete in the case of Saltzmann, (*Ibid.*, p. 30, or *Mém. de Saint Petersburg*, t. III., p. 275.) The same was the case in the patient of M. Graefe, (*Arch. Gén. de Méd.*, t. XVIII., p. 421;) which however did not prevent the wound from cicatrizing, nor life from being prolonged to the period of seven months. The same should be said of the new-born infant, mentioned by Schneider, (Ebermayer, *Journ. Compl.* t. XXXIV., p. 320,) since it became necessary to repeat the operation at the expiration of five years, at which time it proved fatal. Nor could Siebold in his case complete the extirpation of the tumor, for the patient died under his hands. In remarking that he removed all *that he could*, M. Orioli, (*Gaz. Méd.*, 1834, p. 410,) leaves it quite apparent that the disease had not been effectually destroyed in his patient, when gangrene came, so to speak, to complete his operation. Reasoning moreover, would have sufficed to demonstrate what experience has now placed beyond all doubt, to wit: that such attempts were calculated but to augment the danger of an evil, already so formidable and insidious in itself. Such facts, therefore, are not to be taken into the account, when we undertake to determine the value of the operation of extirpation for fungus of the cranium. The small number of cases where the operation has been effectually accomplished, furnish results somewhat less alarming. The Spaniard that M. A. Severin (*Journ. Compl.*, t. XXXIV., p. 300,) states that he cured, could have been so only by the trephine. The same must be said of the patient of Grossmann, (Stoltz, *Thèses de Haller*, 1708, presid. de Sand.) M. Eck says he succeeded without trephining; but he employed caustics after extirpation. I have already remarked that the success of M. Orioli was as much owing to the gangrene as to extirpation. M. Klein twice cured the same patient with an interval of a year, by means of the trephine and extirpation; but he believes the glands of Pacchioni were the seat of the fungus. In another patient the same operation was followed by death, (*Arch. Gén. de Méd.*, t. XXII., p. 225.) In the case related by Volprecht, (Louis, p. 31,) the trephine was applied around the tumor; but this last was not removed, and the autopsy showed that other fungi existed in the cranium. A meningitis caused the death of the patient that Dupuytren had operated upon, (Denonvilliers, *Thèse*, 1789, p. 76,) by embracing the whole tumor in a large crown of a trephine. The patient operated upon by M. Bérard, also it is true died, but it had been rendered necessary to apply *sixteen* crowns of the trephine, and to remove a portion of the longitudinal sinus. M. Pecchioli, in operating upon a man 46 years of age, (*Gaz. Méd.*, 1838, p. 414,) who had a fungous tumor to the right of the sinciput, succeeded perfectly by means of three crowns of the trephine, and by removing a portion of the dura mater. I perceive that M. Syme, (*Edinb. Med. and Surg. Journal*, vol. CXXXVII., p. 384,) going as far down as to the dura mater for a large fungous tumor of the cranium, cured his patient also. If it were proved that the tumor attacked was almost never solitary, these few successes perhaps would not be sufficient to justify the operation of which we are now speaking; but it is to-day demonstrated by the

patient of Pohlius, by that of M. Bérard and by many others, that fungus of the dura mater, like cancer of the breast, is at first quite frequently uncomplicated (unique) ; nor do I hesitate to say that extirpation is indicated at the cranium as in any other region, and that there it presents the same counter-indications as for other cancers. It must, however, be admitted, that in itself the ablation of deep-seated cancers of the cranium is infinitely more dangerous than in any other region of the body, and that these dangers, taken in connection with the unfortunate prognosis which naturally belongs to the disease, are calculated to make us exceedingly circumspect in such cases.

**B. Operative Process.**—If however it should be decided upon, it would be necessary, while taking care to cut the flaps in the sound parts, to preserve as much of the cranial teguments as possible. Crowns of the trephine should then be applied all around the tumor, and the intermediate osseous angles forthwith destroyed by a saw made expressly for this purpose (*ad hoc*), or by means of the chisel and leaden mallet. If the tumor should be situated in the bones only, the surgeon would remove it immediately without incising the dura mater. In the contrary case we should not hesitate to cut round the entire morbid growth, including moreover in the circle a sound margin of the dura mater. Having arrived at this stage of the operation, we ought even to penetrate still deeper if the tumor should be found to have its origin between the pia mater and the brain.

In cases of very large fungus, perhaps it would be advisable to perform the operation at two periods, at an interval of from twenty-four to forty-eight hours, to apply but half the crowns of the trephine on the first day, for example, as M. A. Bérard did, and not to complete the perforation of the bones until the day after, or the day after that, and immediately previous to the extirpation of the tumor. A woman recovered in this way after having sustained the application of *fifty-two* crowns of the trephine, for a large necrosis of the cranium, accompanied with caries, (Méhée de la Touche, *Plaies de la Tête*.) As it is not possible in such cases to unite the wound by first intention, a piece of linen spread with cerate, and perforated with holes, should be extended over the entire solution of continuity. Balls and then gateaux of lint should be applied over this, and kept in place by means of a suitable bandage, so as to fill up the void which has been made in the cranium, and make moderate pressure upon the brain. This last precaution is of the highest importance when we have been forced to excise the dura mater. The patient of M. Bérard, who during the operation had experienced no inconvenience in this respect, swooned away as soon as the tumor with its flap of membrane had been entirely extirpated, and did not come to until after the compression which they had the presence of mind immediately to make, at the place where the parts had just been detached. It cannot be denied also that the sudden abstraction of an abnormal pressure which may have been considerable in its amount, and existed in many cases for several years, must necessarily expose to serious accident in regard to the brain. Extirpation, therefore, of cancers of the cranium, in my opinion, presents but few chances of a favorable issue when the disease proceeds from the pia mater, or where we have to destroy only a somewhat extensive portion of the

dura mater. Consequently then it is for the tumors only with a narrow base, and for such as do not render it necessary to remove anything but the bones, that this operation is in reality admissible. The rest of the manual and its consequences, moreover, are too analogous to those of the trephine, to require that I should say any more on this subject in the present article.

## ARTICLE II.—ENCEPHALOCELE.

There is no resource for hernias of the cerebrum and cerebellum but that of making the patient wear a bandage furnished with an elastic pelote properly adjusted. Every kind of bloody operation would be dangerous and probably cause death, as in the case that Lallement has published, and in that of M. Baffos. Many surgeons, however, have ventured upon its excision. These excrescences from the brain, so frequent in traumatic phlegmasias, and those that follow openings into the cranium, and which M. Champion denominates *hypercephalose*, which Gall considers as the unfoldings of the convolutions, and upon which Langius has written very learnedly, (Epist. 6, liv. I.—Bonet, *Corps de Méd.*, t. III., p. 173,) are attributed by Arne-mann (*Gaz. Sal.*, 1787, No. 59, p. 2,) to the expansion of the anterior ventricle of the brain. It succeeded to a fracture in the case of Tulpus (Bonet, *Corps de Méd.*, t. IV., p. 37, obs. 54,) and in that of Lassus (*Méd. Op.*, t. II., p. 273.) Diemerbroeck (*Anat.*, t. II., p. 235, liv. III., ch. 5,) speaks of one which detached itself several times, and which resulted in death. In the case of Tudecius (Planque, t. XXVII., p. 87,) the cause was the presence of a foreign body, viz., the blunt point of a halberd. In a case where the hypercephalose protruded through the opening made by the trephine, F. de Hilden (Bonet, t. II., p. 374,) states that Bourg had excised it with success. According to Henry Pætrus (Bonet, *Corps de Méd.*, t. IV., p. 49, obs. 73,) extirpation was also performed by Rhodius. The excision of a tumor of this kind, put a stop to the serious accidents it had occasioned in a case related by Trioen and Ravaton, (*Prat. Mod. de la Chir.*, t. I., p. 222, 225,) who advises that they should be extirpated as far forward as possible, (le plus avant possible,) and has often performed this operation without accidents: the pulse after it rose and the head became more free, [i. e. less or rather not at all oppressed any longer by the tumor, T.] Tétu (*Mém. de Méd. Chir. et Pharm. Milit.*, t. XIV., p. 33, et 39,) after having performed excision, had recourse to compression with success. Deidier (*Encyclop. Méth. Méd.*, p. 252, col. 2,) in a case excised many excrescences from an encephalocele without causing pain. It is nevertheless true, that apart from some rare exceptions, I should prefer with Rossi (*Elém. de Méd. Oper.*, t. II., p. 240,) to restrain these tumors by means of plates, or by any kind of compression whatever, rather than attack them with the cutting instrument.

## ARTICLE III.—MELICEROMA,\* (MELIÉCRIS.)

Many persons will carry during their whole life, under the hairy

\* [The Greek coinage of this word is we deem perfectly justifiable, to harmonize with steatoma, atheroma, lipoma, &c. T]

scalp, steatomatous, atheromatous, or meliceromatous tumors, without being sensibly inconvenienced by them or even attempting to do any thing to get rid of them. Others suffer more or less from them and for some reason or another desire at any hazard to be disembarrassed of them.

The nature and formation of these *loupes*, still imperfectly understood, appear, in my opinion, to require further researches. There are some of them which, at their beginning, exhibit themselves under the aspect of a small, hard, yellowish, friable, unorganized mass, similar to collections of fibrine, or blood deprived of its coloring matter and serous portion. Increasing in growth, they begin by becoming soft at the centre, and are thus transformed into a cyst, which is so much the thicker in proportion as the tumor is less ancient or of less volume; a cyst which is filled with grumulous substances, in a greater or less state of fluidity, and which resemble neither pus nor fat. Should we not ascribe their origin to some of the elements of effused blood? It is at least certain that they are not distended cutaneous follicles, as is asserted by Bécларd and M. A. Cooper. Their cyst, which is thicker in proportion to their less degree of development, is always independent of the skin. A tumor twice the size of the head, and which perhaps was only an atheromatous cyst, though the author describes it under the title of lipoma, was removed with perfect success by M. Pl. Portal, from the forehead of a child of four years of age, (*Clin. Chir.*, p. 279.) Sebaceous, serous and other kinds of cysts, lipomas and fibrous tumors, are to be treated at the cranium as in any other part of the body. I have seen sub-cutaneous encephaloid cancers in many individuals, an erectile conical tumor of an inch in length, with a thick pedicle, in a young Moldavian of twenty-four years of age, and melanotic plates of sufficient size in three or four cases. There might be cases where the ligature would suffice to detach them, as in a case related by Boyer, but it is rare they are strangulated at their base. M. Bertrand, (*Arch. Gén. de Méd.*, t. XX., p. 285.) states that he cured one by passing through it a *long needle*, which he kept there in the manner of a seton. Demours, who placed two needles crosswise instead of one, asserts that he thereby obtained successful results. But the cutting instrument here is infinitely better, and ought always to be preferred.

*Operative Process.*—When the tumor is of great size, and the skin much attenuated, an *elliptical flap* of integuments should be removed with the cyst. Two semilunar incisions are then first made. A transverse incision is then made from each lip of the wound, and prolonged outwardly, so as to circumscribe four flaps, which being raised up with care, enable us to remove the loupe entire and without difficulty. In most cases these two last incisions may be dispensed with. While the surgeon, with an erigne or good pair of forceps, draws on the cyst with one hand, he dissects with the other, by means of the point of the bistoury, its external surface, and thus readily succeeds in separating it from the surrounding tissues. In the ordinary process, and where it is unnecessary to sacrifice any part of the skin, it is recommended to make a simple *crucial* or T incision, and to take every possible precaution not to open into the cyst while dissecting the flaps of the wound, which latter is to be united by first intention,

after having extirpated the tumor. M. A. Cooper adopts another course. He first opens freely into the tumor, empties it by compressing it with the thumb and forefinger; then seizes the cyst on one side by the hook or forceps, and dissects and removes it. The incision being made in such manner as to leave intact the posterior wall of the meliceromatous pouch, M. J. Cloquet immediately seizes with a forceps its anterior wall under the right lip of the wound, draws upon it in proportion as he divides the adhesions, which are ordinarily very feeble, and thus effects, to some extent, by a single stroke, the enucleation of the whole cyst. I have, on more than one occasion, confined myself to dividing the integuments only, and then seizing the tumor at the bottom of the wound with a strong erigne, after which it becomes easy to dissect and remove it. By these three variations of the *process of simple incision*, the operation is much more prompt and less intricate than by the ordinary process. After the removal of the sac, the borders of the wound, so to speak, replace themselves in contact, and reunion is generally accomplished in the space of a few days. M. Tealier, (*Transact. Méd.*, t. II., p. 430,) who, after a simple incision, confines himself to making traction on the sac in order to extract it; M. Brachet, (*Ib.*, p. 371,) who removes this cyst after having slit it open and emptied it; and M. Chailly, (*Ib.*, p. 431,) who lays it open and empties it, and then besmears it with red oxyde of mercury; and all which surgeons supposed they had imagined something new, were doubtless ignorant of what I have said above. *The process which I now adopt* by preference, is exceedingly simple; the youngest pupil may perform it with impunity. Having opened into the tumor by puncture with a bistoury or lancet, the same as for an abscess, I seize, with a good pair of artery forceps, one of the commissures of the cyst, which latter I remove by enucleation, separating it by means of the beak of a spatula, as M. Champion does, or by the myrtle-leaf, cataract scoop, the handle of a scalpel, or merely the nail of the little finger. The operation, therefore, is so easy and prompt, that I cannot see what would be the advantage in substituting for it the employment either of *potassa*, as proposed by M. Brachet, (*Ib.*, t. II., p. 371,) Guérin, or M. Canihac, (Rey, *Thèse*, No. 79, Paris, 1834, p. 91,) or the *Vienna caustic*, as eulogized by M. Hennau, (*Transact. Méd.*, t. II., p. 385,) and by M. R. Gérardin, (*Journal des Conn. Méd. Chir.*, 1837.) It is nevertheless true that, like every other operation, it sometimes gives rise to serious accidents. In a case cited by M. Merat, (*Transact. Méd.*, t. XI., p. 432,) it was followed by tetanus. A female patient, who was operated upon for it in 1825 at the hospital of the Faculty, was seized with an extremely dangerous erysipelas; and in another woman it caused her death. But these are very rare exceptions, which do not take place in one case out of fifty. The wound almost always heals in less than eight days. Left to itself, moreover, the tumor increases in size, and may be transformed into cancer. This is what took place in an old man I operated upon in 1836, and in a woman aged seventy years, whom I operated upon on the 12th of January, 1839. I have removed as many as eleven of these tumors at one sitting. Some patients also have their cranium as it were covered with them.

## ARTICLE IV.—HYDROCEPHALUS.

The principal operation which has been proposed for hydrocephalus is puncture of the cranium. Holbrock and Vose (Dugés, *Manuel d'Obstétrique*, &c.,) profess to have performed it, or to have seen it performed with success. Rossi (*Médecine Opératoire*, t. II., p. 46,) has drawn in this manner, at several times, six pounds of serosity from the cranium of a child eleven to twelve years of age, and who got well. M. Syne, in 1826, had recourse to it five times on the same child, in the space of a few months, and each time with some apparent advantage, though the little patient ultimately perished. M. Greatwood (*The Lancet*, 1829, vol. II., p. 238,) succeeded with it in one case, and M. A. Cooper appears once to have obtained partial success from it. M. Bédor, (*Gaz. Méd.*, 1830, p. 188,) who has also made trial of it, likewise believes that it may answer. But the injury done to the brain by hydrocephalus, is ordinarily too deep-seated for a simple puncture in such cases to restore the health. Nevertheless, should it be decided upon, nothing is easier to do than this, either with the lancet, bistoury, or a small trochar. There would be no other precaution to take than to avoid with care the track of the venous sinuses. Upon the supposition that we did not wish to draw off at once the entire amount of the liquid, I would much prefer repeating the operation from time to time, rather than to leave a canula resting in the wound, as has been proposed by Lecat. As to the rest, it is an operation which now counts a great number of trials. Theodoric (Portal, *Hist. de l'Anat.*, etc., t. I., p. 185,) had already made the remark, that hydrocephalous children treated by the application of the red hot iron to the forehead or the occiput, had ultimately recovered. It appears also that S. Chabbi (Hévin, *Path. Chir.*, t. I., p. 232,) had performed it with success. Also in cases of this disease where it would seem to be required, other surgical means have been resorted to. Warner (*Obs. de Chir.*, obs. 11., p. 69,) says that in a case in which extirpation for a *hydrencephalocèle* was performed against his advice, it caused death; and Thiebaut (*Journ. de Desault*, t. III., p. 327,) gives the history of two similar attempts, which were followed by the same result. A case also operated upon in Scotland, and in which a *hydrencephalocèle* that projected above the nose was excised, terminated fatally. Leveillé (*Nouv. Doct. Chir.*, t. III., pp. 47, 48,) who relates this fact, says the same thing took place at Gottinguen. In the case of an infant aged seven months, in which the tumor, projecting through the parietal bone, was cut into by Rambaud, (*Journ. de Dehorne*, t. IV., p. 212,) death in fact followed on the day after the operation. The case of an infant mentioned by Sulpius, (Bonet, *Corps de Méd.*, t. IV., p. 6, obs. 7,) was no less unfortunate. I have seen, says M. Champion, two infants die, who were operated upon for this disease in spite of my advice to the contrary, one at the forehead, and the other near the occipital hole. The first died the day after the application of the ligature, which had been placed around the tumor; the other survived only some hours after the ligature had been applied, followed by excision of a *hydrencephalous* sac of considerable size.

Puncture of the cranium also for hydrocephalus was performed in France before the English surgeons had received it. Pelletan (Heurtault, *Consider. sur Diff. Points de Chir.*, p. 111, 1811,) had recourse to it at the Hotel-Dieu of Paris, the 7th Thermidor, and year VII, on an infant aged twenty-two months. A canula was left remaining in the parts, and the patient died at the expiration of five days. Besides the above examples, we might mention at the present time many other instances of puncture of the cranium in cases of hydrocephalus. Thus M. Graefe (*Arch. Gén. de Méd.*, t. XXVIII., p. 409,) and M. Russel (*Gaz. Méd.*, 1832, p. 641,) have each had a successful case. M. Hoefeling (*Encyclogz. des Sc. Méd.*, 1838, p. 251,) gives a case of hydrocephalus in a child aged five years, who having received a kick from a cow, had the cranium fractured and was thus cured of his disease. I will add that M. Allaire, (*Jour. des Conn. Méd. Chir.*, t. II., p. 305,) who drew by this operation, repeated three times in one month, six ounces of liquid at each of the two first punctures, and four at the last, had not the same success, as his patient died soon after. It is nevertheless true that the cases of M. Conquest (*Gaz. Méd.*, de Paris, 1838, p. 251,) are now sufficiently numerous to merit all the attention of practitioners. In his last table this practitioner relates *nineteen* cases of this operation performed by him during the last ten years. In the first of his cases, M. Conquest, who made but one puncture, drew off 32 ounces of liquid, and obtained complete success. The second underwent three punctures, which yielded thirty-four and a half ounces of serosity, but ultimately ended in death. The third recovered after two punctures and the evacuation of twenty-four ounces of liquid.

In the fourth, death occurred after the fifth puncture and the removal of  $48\frac{1}{2}$  ounces of fluid (de matière.) The fifth died also after four punctures, which furnished 45 ounces of serum; the sixth was cured by the extraction of 26 ounces of liquid in three punctures; whilst in the 7th, 8th, 9th, and 10th, who died, as well as the 12th and 15th, it was not practicable to make [respectively] but two, one, two, two, one, and four punctures, which obtained 20, 8, 22, 17, 7, and 33 ounces of serosity. The 11th, 13th, 14th, 16th, 17th, 18th, and 19th, which recovered, furnished [respectively] 55, 13, 9, 6, 31, 14, and 9 ounces of liquid, by means of 5, 1, 2, 4, 3, 2 and one puncture for each; from whence we have 9 deaths and 10 cures, on the total amount above mentioned. If it were allowable to count on so large a proportion of successful cases as this, there could be no doubt that paracentesis of the cranium ought to be practised in cases of hydrocephalus. But, on one hand, the observations of Pelletan, many similar attempts, collected in the practice of Dupuytren, together with the facts of M. Bedor and M. Allaire, show that up to the present moment, it has scarcely ever succeeded in France. On the other hand, when we reflect upon the possible chances that certain patients might have of living a long time with a hydrocephalus of considerable size, while by puncture they generally succumb at the end of a few days, we have good ground for not deciding upon this operation without some apprehension. In the halls of the Clinique of the Faculty, I have seen a hydrocephalous child of from 5 to 6 years of age, who in other respects appeared to be in sufficiently

good health. I have also had an opportunity of seeing a child of from four to five years of age, who had the cranium *quadrupled* in volume, and which a man hawked about the country to exhibit as a curiosity. A hydrocephalus of considerable size, did not prevent a patient who was for a long time seen at the hospital of Perfectionnement, from living to the age of 25 or 30 years, and Maréchal gives an instance of a patient with hydrocephalus, who attained to his 70th year. These, however, are but rare exceptions, and no one will dispute that hydrocephalus is almost a certain cause of death. A consideration, moreover, which would perhaps influence me in such cases is this, that the existence of hydrocephalic subjects, being accompanied with more or less complete paralysis, and an absolute annihilation almost of the intellectual faculties, is reduced in fact to a vegetative life, and can be of no great moment either to society, the family, or to the individual himself; from whence it follows, that without deceiving ourselves as to its importance, we ought, nevertheless, to have recourse to this operation in patients who seem in other respects to be placed under the most favorable conditions possible.

#### ARTICLE V.—SPINA BIFIDA.

We ought, perhaps, to have treated of spina bifida, under the chapter on Serous Cysts. But the relations of this description of tumor with the encephalon, have in some sort forced me to examine it immediately following hydrocephalus. Modern surgeons believing that they had established the fact that spina bifida always communicates with the arachnoid or sub-arachnoid cavity of the spinal marrow, have thence concluded that it was a disease placed beyond the domain of operative surgery. Under that view the same opinions have been expressed of this disease as of hydrocephalus, of which spina bifida was considered as nothing more than a dependence or variety which might be called *hydroschisis*. On the one hand, however, it may be supposed that many serous cysts, noticed on the posterior plane of the spine, do not communicate with the envelopes of the spinal marrow, and that they originate outside the dura mater. This is nearly demonstrable, especially in one of the patients operated upon by M. Trowbridge, (*Journ. des Progrès*, t. XVII., p. 274,) and who had a serous cyst, with numerous cells, in the lumbar region. On the other hand, we possess, at the present day, sufficiently numerous examples of cures of tumors of this description obtained by various operations. An infant a year old, and who had one of these tumors along the vertebral column, was relieved of it by means of five punctures (*mouchetures*, see Vol. I.) by M. Labonne (*Revue Méd.*, 1826, t. II. p. 281,) who professes to have in this manner cured a spina bifida.

An infant aged three months, and who had had a similar tumor from its birth, was submitted to puncture by M. Probart, (*Biblioth. Médic.*, 1828, t. II., p. 120.) Erysipelas and convulsive movements supervened; leeches, purgatives and plasters were had recourse to, and the cure was accomplished. M. A. Hawarden (*Ibid.*) is referred to for a fact in every respect similar, and which possibly might be the same. Two examples of successful results obtained

by small punctures on tumors which were situated on the posterior face of the sacrum, have been related by M. Bozetti, (*Journ. des Progrès*, t. V., p. 253.) An interesting case of this kind has been given by M. Wardrop, (*The Lancet*, 1828, vol. I., p. 308.) The tumor, which was also situated upon the sacrum, was fourteen inches in circumference. After several punctures, it was found at the expiration of six weeks to have been reduced two thirds of its dimensions. But convulsions and death, which then took place almost suddenly, afforded an opportunity of proving that the serous pouch communicated directly with the vertebral canal, and that the spinal marrow was sound. M. Trowbridge, of whom I have just spoken, states that he has in two instances succeeded by excising these tumors after having submitted them to a gradual constriction (constriction). From whence it follows, as it appears to me, either that many of the cysts described under the name of spina bifida, do not communicate with the interior of the spinal membranes, or that hydrorachis with hernia of the cyst, is not absolutely incurable. According to this induction we should naturally be led to conclude that it is proper to treat spina bifida by surgical means. In these cases I think we have it in our power to lay down the following rules: 1. If the tumor is not accompanied with paraplegia and the cyst is not too much attenuated, we ought to wait and confine ourselves to the use of topical astringents or compression; 2. Although there may not be paraplegia, if the cyst is very prominent and with a large base, we should perform the puncture with a lancet rather than with a trochar, and repeat the same operation weekly, at the same time that astringents and compression should also be used; 3. Whether the cyst be attenuated or not, or accompanied or not accompanied by paraplegia, it should be strangulated at its root provided it is pediculated; and we should wait until it is shrunk before incising it outside of the constricting ligature; 4. When paraplegia is present, whatever be the form, volume or thickness of the cyst, the treatment to be employed by preference is repeated punctures. Though the surgeon ought to hesitate with a child who is in other respects in the enjoyment of perfect health, the case, in my opinion, is very different when complicated with a profound alteration in the functions of the spinal marrow. In this state the little patient is devoted to a certain death if nothing is done, and we have seen by what precedes, that by means of an operation there is some chance of saving him. In 1824 I saw at the hospital of Perfectionnement, an infant two months old, who had at the point of the sacrum a serous cyst, which was flattened in shape, of a reddish color, and of the size nearly of the fist; and which was ultimately cured by means of four punctures practised during the space of a month, together with compression, aided by topical astringents, continued about five months. A young boy whom I saw at the Hotel Dieu, in 1835, had on the base of the sacrum a transparent tumor, existing there for several years, and having the size of a large pullet's egg, and which certainly would have received the name of spina bifida, if it had been met with in a new-born infant. I have since learned that this tumor, treated by puncture and afterwards by incision, had ultimately entirely disappeared. As for the rest, it is at the base of

the lumbar region, and on all the posterior surface of the sacrum, that the operation in my opinion presents the best chances of success. There in fact there is no longer any spinal marrow, and the inflammation must necessarily be less dangerous than in the other regions of the spine. Certain it is that, restrained by this idea, I did not venture to meddle with a spina bifida which was situated in the cervical region, another which was found near the middle of the dorsal region, nor a third which was sent to me in November, 1838, by M. Larrey, and which had its seat in the upper part of the lumbar region. I have, however, at the *maison de santé* of M. Dufrenois, made trial of repeated punctures with the lancet on a spina bifida in this last-named region, in a new-born infant. The tumor had the dimensions of two five-franc pieces; its walls were thin and of a bright rose color, and threatened to become ruptured; a first puncture sensibly diminished the paraplegia; it was the same with a second and third, and finally with the fourth. But on the twentieth day, convulsions and other signs of arachnitis announced to us that the scene was changed; death took place at the end of the month, and the opening of the dead body performed by M. Behier, in presence of M. Guersent, showed that a purulent inflammation which had commenced at the cyst, had extended itself throughout the whole length of the spinal marrow, reaching into the cranium. I will add to these details, that in the last century, Orth, (*Thèses de Haller*, t. V., p. 218, Juillet, 1719, French translation,) following Salzmänn, had already endeavored to make it appear that certain cysts which are developed along the track of the spine ought not to be confounded with spina bifida, and that in our time, M. Busche (*Revue Méd.*, 1829, t. IV., p. 118,) has exerted himself to prove that many of those cysts were partitioned (*cloisonnés*) like the ovaries, and without communicating with the cephalo-spinal cavities. The four examples related by this last author, are calculated in this respect to inspire practitioners with a certain degree of boldness. Finally, the case of an infant seven months old, who had in the lumbar region a legitimate spina bifida, which Skimer (*Arch. Gén. de Méd.*, 3e serie, t. II., p. 494) attempted to treat by repeated punctures, was not more fortunate than the one I have mentioned above.

#### ARTICLE VI.—CEPHEMATOMA (*Sanguineous Tumors of the Cranium*).

Sanguineous cysts of the cranium are sufficiently often encountered in new-born infants to induce many practitioners to consider them a specific disease, generally known at the present day under the name of cephematoma (*céphalématome*). Having elsewhere (*Art des Accouchements*, t. II., p. 590, 2e edition) treated of these tumors, I will now speak of them only in their connection with operative surgery. These cysts, moreover, have been sometimes confounded with encephalocele, as is proved by the observations of Le Dran, Trew, M. Michel, and some others. M. Champion informs me that he has seen a surgeon, in other respects a man of great experience, make also a mistake of this kind a short time since. We should, moreover, be deceived if we calculated on finding cephe-

matoma only among new-born infants. Since the publication of the work above cited, I have met in an infant twenty months old, with a sanguineous cyst of more than three inches in diameter, and which covered almost the whole of the frontal bone. Another infant, aged six months, whom I saw with Dr. Demey, had one of similar dimensions on the left parietal bone and a portion of the occipital. A woman, aged 49 years, and a man 26 years of age, presented to me similar examples, one on the right region of the forehead and temple, the other on almost the entire right half of the cranium. Other analogous facts, but less striking than those last mentioned, have also assisted in confirming me in my first opinions on the mechanism and nature of sanguineous tumors of the cranium, to wit: that these cysts are formed by an effusion of blood, which takes place in consequence of vascular rupture or spontaneous exhalation, sometimes between the skin and aponeurosis, more frequently between the aponeurosis and pericranium, quite frequently also between the pericranium and bones, and sometimes between the bones and dura mater. A case noticed by M. Neve (communicated by the author to M. Champion,) would go, in fact, to show that the blood primarily extravasated between the dura mater and cranium, may transude and pass through the bones, and arriving externally, constitute a thrombus or cephalematoma. The mode of curing these tumors is not considered in the same point of view by all practitioners. Puncture, followed by compression and topical resolvents, have obtained decidedly successful results with M. Champion. Others have had the boldness to recur to large incisions, and even to the seton; but I have satisfied myself that with a little patience and some topical astringents, we may almost always succeed in dispersing the tumor without the necessity of an operation. The cephalematoma which I treated in this manner, in consultation with M. Cisset, disappeared at the expiration of a few weeks. The child that M. Démev sent to me, got well in fifteen days. I have seen others which recovered still more rapidly. In the man and woman whom I have mentioned above, the tumors, notwithstanding their extreme dimensions, receded more and more, and ultimately disappeared in the space of a month. It is however true, that in the patient first mentioned, after having made a puncture on the forehead and extracted from it four to five ounces of a sanguinolent liquid, I found that the walls of the tumor agglutinated, and that a complete cure followed.

In conclusion, then, I would, in these cases, advise temporization, afterwards compresses wet with a solution of muriate of ammonia, tannin or alum, or some other astringent liquid. Puncture would not be admissible until after unavailing attempts by compression, or unless at the end of a month's treatment, the tumor remaining stationary, seemed rather to have a tendency to increase. Pure and simple puncture will then, in most cases, succeed, especially if we associate with it for some days a slight degree of compression properly applied. To cover the whole extent of the cyst with a temporary blister, would also be an excellent remedy as an adjuvant to puncture or the simple incision; but the most certain remedy in all these old cases, and especially where the cyst contained scarcely any thing but liquid matter, would be the iodine injection, the same as in cases of

hydrocele. I would not, in fine, decide upon laying open the tumor largely or on many of its points until after having made use of all other means, or unless there should exist some serious accident, or that a suppuration kept up by the cephalematoma had actually become established.

#### ARTICLE VII.—OPERATIONS REQUIRED BY THE DISEASES OF THE FRONTAL SINUS.

There are two regions in the cranium where the diseases may require operations so diversified, that we are almost tempted to make them the subject of two special articles. These regions are the frontal sinuses, and the mastoid process; but as it is next to impossible to separate what relates to this last from the operations required for the diseases of the ear, I shall not treat of it upon the present occasion, but speak only of what relates to the frontal sinus, properly so called. Operations have been performed upon the frontal sinus, in cases of fractures, caries, necrosis, abscesses, hydatids, polypi, the presence of foreign bodies, collections of fluid, and various kinds of degeneration. The relations of the frontal sinus with the interior of the nasal fossæ, and with the cranium and orbit, will always render its diseases difficult to diagnosticate and cure, at the same time that they generally increase their danger. The operations which they render necessary must, moreover, in their nature be sufficiently delicate, and sometimes in themselves formidable.

##### § I.

When from a *fracture in the forehead*, some fragments remain displaced posteriorly, in such a manner as to give rise to accidents, it may become advisable to remove the anterior wall of this sinus, either wholly or in part. Facts of this kind have been related by Fallopius, Trew, Maréchal, Colignon, Jackson and many others. In a patient whose case is given by Horne, (*Acad. de Chir.*, t. VI., p. 203, in 12°) there was a fracture at the superciliary ridge. The ablation of the osseous projection was effected; accidents supervened, and bleeding had to be resorted to eight times; but the patient recovered. Lassus (*Méd. Op.*, t. II., p. 259) and M. Larrey, as well as Fichet de Fléchy, (*Observat. de Méd. et de Chir.*, p. 213,) have related examples of cures obtained in the same way, and without the patients having been exposed to the slightest dangers. Muys, (*Nouv. Obs. de Chir.*, p. 438, obs. 5, decad. 8.) who was already aware that the opening into the frontal sinuses has a tendency to become fistulous, and who, on that account directed his attention to the passage of the air, and then to the rolling up (*recoquillement*) of the skin, recommends that we should be careful to contract (*raccourcir*) the borders of the wound in a proper manner immediately after the operation. It is readily conceived also, that in cases of fracture it may sometimes become necessary to enlarge the pre-existing wounds, at other times to establish new ones, also that if the fragments are somewhat loose, we may be enabled to detach them by means of a good pair of forceps, while, on the other hand, if they remain adherent at some point, it

may become necessary to employ the osteotome, gouge, mallet and trephine. In these cases, the surgeon should not forget that purulent collections are especially to be apprehended in the direction of the orbit, and that in order to prevent them, there is no better method than to leave or to establish a free issue for the fluids in this quarter. The incisions required, therefore, should be placed as much as it is possible to do so, rather below than above the eyebrow. I will add, that it is better to make them large than small, and that the cutting pliers, modern osteotomes and trephine should be employed in preference to the chisel or hammer, whenever their application would not seem to be attended with too much difficulty, or except the slightest danger was to be apprehended from any concussion upon the cranium. It would appear that Langguth (*Thèses de Haller*, translation, t. I., p. 125) had foreseen this danger when he advised the employment of the scissors rather than recur to the trephine. O. Acrell, (Sprengel, *Hist. de la Méd.*, t. VII., p. 31,) on the contrary, confined himself to trephining upon the superciliary ridge, in a patient where the frontal bone had been fractured and driven in. In spite of the unsparing censures of Bertrandi, in 1763, on the use of the trephine to the frontal sinuses, and the accusation he makes against it, of leaving an incurable fistula, and of being inconvenient in its application, M. Larrey (*Campagnes Chirurg. d'Egypte*, p. 136) employed it with advantage, even in perforating through the cranium; Collignon (*Biblioth. Chir. du Nord*, p. 179) speaks of a fragment of ball which, having become arrested in the upper eyelid, produced an exfoliation of the anterior wall of the frontal sinus, without being followed by any fistula; and we find in the Memoir of M. Gaultier de Claubry (*Bull. de la Fac. de Méd.* t. III.) a great number of instances where trephining of the frontal sinuses was evidently attended with utility.

## § II.—*Caries and Necrosis.*

Caries and necrosis of the frontal sinuses are a double disease, which there, as elsewhere, are sufficiently often found blended together. Béranger de Carpi and Dulaurens (Portal, *Hist. de l'Anat. et de la Chir.*, t. VI., p. 491) had already noticed that the vault of the frontal sinus was sometimes perforated with holes and, as it were, worm-eaten, and to such extent as to allow of the fluids penetrating into the cranium. Similar facts have since been pointed out by Fabre, (*Ib.*, t. XI., p. 164.) Sellien (*Biblioth. Chir. du Nord.*, p. 100) gives a case of venereal caries, with fungosities of the frontal sinus, and which he cured by means of red precipitate. A man had a caries with softening of the internal orbital process; Janin (*Mémoire et Observations sur les Maladies des Yeux*, p. 290) having made an incision, then excised a portion of the lips of the wound, and removed all the bone he could by means of the bistoury. Camphorated oil was then applied to the remainder of the caries, which ultimately exfoliated and allowed the whole wound to cicatrize. Delpech (*Révue Médicale*, Mai, 1838) speaks of a necrosis, the extraction of which left a large opening into the nose and frontal sinus, which opening he treated by rhinoplasty. The frontal bone was altered to the extent of an inch; a crown of the trephine and some strokes upon the gouge

removed the caries entirely. Obstinate hemorrhages took place at first, but the patient nevertheless, says Cavalier, (*Société de Médecine de Marseilles*, 1817, p. 38,) got well in the space of a month. M. Riberi, (*Gaz. Méd.*, 1838, pp. 795, 796,) in two cases with caries, accompanied by necrosis of the frontal sinus, was not enabled to succeed, except by means of the gouge and mallet. So that examples at the present day are not wanting to show the resources of surgery in cases of necrosis or caries of the frontal sinuses. In these cases, the operation to be preferred is the same as for caries or necrosis in general. It ought moreover to vary according as the disease is more or less extensive, or according as it exists in a simple state, or with different complications. Should the soft parts be sound, it would be advisable to cut from them a semilunar flap, with its free or convex border turned upwards and inwards, so that its lower extremity might terminate on the ascending process of the maxillary bone.

In cases where ulcers and fistulas existed, all that would be required perhaps would be, to enlarge them without making any distinct incisions. In whatever way we have proceeded in laying bare the diseased region, we should, in order to complete the operation, employ the forceps to extract the movable fragments, the bistoury, or a strong scalpel to destroy the softened bones, the chisel or the gouge and mallet, if there were only some splinters to remove, the cutting pliers, or Liston's scissors, in cases where the diseased portion might be very projecting and well circumscribed, and the osteotome of M. Heine or M. Charrière, or even the trephine rather than strokes with the chisel, should it be necessary to go down deep and take away a large portion of bone. Caustics and the red hot iron employed by some surgeons, and again recently by M. Riberi, would not be advantageous in such cases, unless we had to destroy simple fungosities, as in the case related by Sellien, or thin lamellæ.

### § III.—Abscesses.

Caries and necrosis of the frontal sinus frequently result from an abscess which has formed in the interior of this cul-de-sac. The pus confined in an unyielding cavern, ulcerates the mucous membrane which lines it, denudes it, soon mortifies its walls, and finishes by making a passage to itself, either in the direction of the orbit, or the nasal passages, or even into the interior of the cranium; but besides that such purulent collections in themselves involve sufficiently severe dangers, there may also result from them fistulas or an alteration of the bone which could scarcely be cured but by one of the operations which have been described above. It would be advisable, therefore, to remedy the difficulty in the beginning, if it can be done. Although Borelli, Bartholin, Boetius, Tulpius, Marchettis, Chevassieu, D'Audibert and Celier, have seen cases where abscess in the frontal sinus has got well by making its way through the nasal passages, Richter (*Bibl. Chir. du Nord.*, p. 242 to 249,) nevertheless advises that we should endeavor to re-establish the natural passages, or to create a new one, rather than to destroy the mucous membrane of the sinus. Sauvages, (*Nosologie*, t. VIII., p. 345,) who first makes trial of detergent injections, also prescribes the trephine. An abscess

of the frontal sinus having invaded the ethmoid bone, led to the supposition that it had extended to the maxillary sinus, which was unnecessarily perforated. Other remedies, says Jourdain, (*Maladies de la Bouche*, t. II., p. 101,) directed to the frontal sinus, effected the cure of the patient. In another, Jourdain (*Op. cit.*, t. I., p. 78,) destroyed the anterior nasal wall of the maxillary sinus, in order to reach into the frontal sinus, which was filled with pus, and to introduce injections into it; Frank (*Médec. Prat.*, t. V., p. 38, French translation,) says a physician of Vienna has frequently trephined the frontal sinuses in order to extract from them inspissated mucosities. I should certainly however not recommend that we should go to the extreme of trephining the forehead, for the sole purpose of extracting mucosities or some few drops of pus accumulated behind the internal orbital process. So long as the collections in this cavity have not disorganized its walls, there is reason to hope that they will make their way through the nares; and this is the termination which we ought to encourage by means of fumigations, injections, or even sternutation, before thinking of the trephine. But should the disease have been of long standing, and have resisted every thing, and caused violent pains and severe accidents, and that its diagnosis can be clearly made out, trephining in my opinion would be the best remedy. Two processes may then be employed: either after the manner of M. Riberi, we may incise the soft parts in the upper portion of the great angle of the eye, and perforate with a punch or the perforating trephine, or with the scalpel only; or what is better, with a small crown of the trephine, the upper part of the os unguis, or the ascending process of the maxillary bone, and the extremity of the internal orbital process, in such manner as to penetrate into the nares and create there a passage for the liquids, and to be enabled to shut up the solution of continuity in good season, without having any apprehension of the formation of a fistula. It is important under such circumstances to avoid wounding the lachrymal sac, and the tendon of the orbicularis muscle; also, it would be advisable to cut out a semilunar flap whose free border should look inwards and forwards. No doubt this method would be successful, if the collection in the frontal sinus was prolonged very far downwards, and if it were not yet complicated either with caries or necrosis. Otherwise it is better directly to attack the frontal sinus itself; taking care if it is not yet ulcerated to open it at its most depending part, that is to say, between the upper eyelid and the top [or the inner extremity (*la tête*)] of the superciliary ridge. The operation moreover would, in almost every particular, be the same as that which I have pointed out in the preceding case. It would differ from it only in having to prolong the incision in the form of an arc a little higher up and somewhat more outwardly, and that the trephine and perforators would act exclusively on the frontal bone, instead of including at the same time both the maxillary bone and the os unguis.

#### § IV.—*Foreign Bodies.*

Besides pus, there have been found in the frontal sinuses, under the character of foreign bodies, clots of blood, polypi, stones,

worms, &c. Chaptal, the father, (Sauvages, *Nosologie*, t. VI., p. 177.) having noticed that pains of the head which had persisted with violence for a long time, disappeared in consequence of a nasal hemorrhage, concluded on that account, without, as it seems to me, being perfectly authorized to do so, that blood retained in the frontal sinus had been the cause of this suffering. Instances of calculi in the frontal sinus, related by Bartholin, F. de Hilden, and Schenckius, are somewhat more positive, since an opportunity presented of identifying the objects by direct observation. The same may be said of the cases of a *tent* there mentioned by Hølegost, and also those of a *ball* which, according to Zacutus Lusitanus, would constitute conditions calling for the application of the trephine. Cesar Magatus (*Journ. Gén. de Méd.*, t. XLV., p. 331,) says a patient was cured by trephining his frontal sinus for a *worm*, and Rossi (*Médec. Opér.*, t. II., p. 116, note 5,) had recourse to this operation in order to place a ligature around the root of a *polypus*, which he afterwards extracted through the nares. A fistula which was thereby caused in this case, lasted for the space of three years, and was not cured until after the rupture of the osseous lamina which separates the sinus from the nasal cavities. In the case of M. Hoffman (*Rév. Méd.*, 1826, t. II., p. 152,) it became necessary after the extraction of the polypus, to pass a seton from the sinus into the nose. M. Langenbeck (*Biblioth. Chir.*, or S. Cooper's *Dictionnaire de Chir.*, t. I., p. 439,) finding a large tumor external to and above the root of the nose, had recourse to the trephine in order to open into it, when he recognized that it was made up of an enormous *hydatid mass*. A cavity two and a half inches deep remained at the place which the tumor had occupied. Other foreign bodies also have been noticed in the frontal sinus: Salzmann (*Convulsions des enfans*, p. 248,) states that he has found and killed worms there. M. Maunoir (*Questions sur les corps étrangers*, p. 204,) and also M. Breschet (*Dict. des Sc. Méd.*, t. VII., p. 4,) speak of *balls* retained in this cavity for the space of three months. M. Larrey (*Campag. Chir.*, t. IV., p. 89,) relates that the Chevalier Erasme retained the point of a *javelin* for fourteen years in the frontal sinus. M. Dezeimeris (*L'Expérience*, t. I., p. 572,) has extracted from the cartons of the ancient Academy of Surgery, the case of a fungous tumor of the form of the patella, and which was situated in the frontal sinus. M. Brunn, (*De Hydrope Cystico*, &c., Berlin, 1829; *Journ. des Progrès*, t. II., sér. 2, p. 255; *L'Expérience*, t. I., p. 568,) a Prussian surgeon, speaks of a young girl who, being tormented by a supra-orbital tumor, died after having been submitted to a crucial incision upon the same and the employment of the seton. Now this tumor, which was attended with a sero-sanguineous liquid and a fetid suppuration, and which was five and a half inches long and four and three-quarters in breadth, situated in the frontal sinus and composed of cells or small bladders, which had become developed in the space of five years, might have evidently been extirpated if it had been attacked at an earlier period and in a proper manner; an instance of a hydatid tumor of the forehead had already been mentioned by M. Corby, (*Biblioth. Médic.*, 1829, t. III., p. 20,) but in this case the disease was altogether independent of the sinus. The presence of foreign bodies in the frontal sinus would still

more positively call for the application of the trephine than any other of the diseases of which I have hitherto spoken. Their diagnosis, therefore, is a point of great delicacy. As to the operative manual here, also, two modifications would be offered, according as the sinus was intact or already laid open. In the first case it would be necessary to cut down in such manner as to lay bare the tumor extensively, and in preference by the semilunar flap which I have indicated in the beginning. The crown of the trephine would be better adapted here than any where else, and even than the other osteotomes: only that it would be advisable to apply two small ones, one on the side towards the orbit below, the other at the top [inner extremity] of the superciliary ridge above, which should be done in order to obviate the inconveniences which result from the irregularities of the frontal bone in this region. The points, bridle or bridge left between the two crowns, could afterwards be easily destroyed by means of the scalpel, cutting pliers or chisel. Should there have already existed any fistulas or ulcerous passages, they could be made use of as a guide by which to reach the foreign body, and the enlargement of these might be all that was required to give to the incisions the form and extent that were necessary. I have no need of remarking that the foreign body itself when once laid bare, may require the aid of the forceps, even the cutting pliers, and elevators and ligatures, and the use of the bistoury and dissections, more or less cautiously conducted, according as it is movable in the sinus or implanted in the bones, or is in a fluid state or concrete. This remark applies also to necrosis as well as to foreign bodies.

### § V.

Though the immediate consequences of this operation might be serious, they are nevertheless ordinarily very simple. One of the most disagreeable is that of often leaving a fistula, which is exceedingly difficult to close up. I have, however, seen this fistula heal up in two instances in patients who had the anterior wall of the frontal sinus destroyed by necrosis, and in a third in whom this wall was lost in consequence of a comminuted fracture. That of P. Gerardi, after receiving no benefit from the dilatation of the frontal sinus through the nares, yielded to the action of a machine similar to that which F. ab Aquapendente and Petit made use of to compress the lachrymal sac, a contrivance which Rossi, (*Médec. Oper.*, t. II., p. 244.) who does not pretend to have invented it, calls a presser (pressoir), and which M. Riberi, who again revived it in 1838, appears to have employed like his countryman, but without obtaining, however, any real advantages from it. Perhaps it has not been sufficiently examined in these cases if the interior of the sinus was perfectly free of disease. I suspect, in fact, that the fistula here depends chiefly upon certain particles of altered bone, or ulcerations, or points of caries, much more than on the physical and natural disposition of the sinus. I would, therefore, advise before all other steps, that we should carefully explore the parts and remove from the region every thing which has the least appearance of disorganization. If after this, lotions and detersive and astringent injections, and even slight cauterizations should not suffice, I

would then willingly give the preference to perforation of the inner wall of the sinus in its lower portion, and in such manner as to make it communicate freely with the nose. Rossi (*Méd. Oper.*, p. 116, note,) by dilating the internal orifice and breaking the nasal wall of the sinus, succeeded completely. Perhaps even an opportunity would here offer of inserting a large and somewhat short canula constructed after the model of lachrymal canulas. In conclusion, the facts which relate to the operations required for the frontal sinus, are so dispersed through works of science, and given mostly with details so vague, and these operations have been so rarely performed with us, that it would be difficult at the present time to subject them to general rules that are either very precise or very useful. [See a note farther on. T.]

## CHAPTER II.

### FACE.

The operations which are performed on the face are numerous and varied, but many of them have been described elsewhere, (see Vol. I. and Vol. II. of this work, on the respective subjects of *Anaplasty*, *Exsections*, and *Tumors*.)

#### ARTICLE I.—OPERATIONS WHICH ARE PERFORMED ON THE NOSE.

I have not to consider here the different forms of rhinoplasty, the details of which will be found under the chapter on *Anaplasty*, (Vol. I. See also our *notes* there.)

#### § I.—*Tumors*.

Tumors of various kinds may be developed in the nose, the same as in any other region. As I shall have to treat of polypi of the nasal fossæ after having spoken of the operations which are performed on the velum palati, I do not design at the present moment, to touch upon any other than tumors which are situated in the substance of the nose, properly so called. As respects the operation they require, these tumors form two classes, some of them having their seat on the body of the organ, others in the septum.

A. *The nose, properly so called*.—I. We find on the body of the nose three principal varieties of tumors which occasionally require the aid of operative surgery. These are worms (*tannes* or *maggots*), cancers or elephantine masses. In no region, perhaps, are the *sebaceous follicles* more frequently altered than upon the nose. So long as the substance with which they are filled does not exceed the dimensions of a pin's head, and are unattended with any degenerescence of the cutaneous tissue, the disease would not justify any kind of operation. On the contrary, should the crypt itself become thickened and transformed into a tumor which had acquired the size of a bean or the

head of a nail, it might be advisable to attack it by other means than by simple pressure. In such cases the subject of extirpation might be taken into consideration; but cauterization with a crayon of nitrate of silver cut into the shape of a cone, with its point carefully introduced into the aperture and down to the bottom of the sebaceous follicle, will almost always answer. If the tumor were still more developed; if, for example, it exceeded the volume of a small nut, and presented itself under the aspect of a cyst with thin walls, filled with matter of a purely fatty character, then extirpation would evidently be preferable. [See our note above, pp. 60-63, giving the case (with plates) of those enormous tumors of this kind, which I successfully removed at Nassau, capital of the Bahamas, in 1824. T.]

II. Tumors and *cancerous* degenerescences of the nose usually exhibit characters that are altogether peculiar. They are usually rather plates, bumps, (bosselures,) or incrustations, than tumors that are exactly circumscribed, or that can be arranged under scirrhus, or those that are encephaloidal, or melanotic, or of the colloid tissue. Their origin most frequently seems to be connected with a vitiated secretion or degenerescence of the sebaceous follicles themselves. In all cases these tumors, which are usually badly defined, and scarcely found except in persons advanced in age, exact certain precautions in a surgical point of view. The treatment by caustics generally succeeds with them perfectly well. A lady who had one of the diameter of an inch for many years, was cured by means of four cauterizations with the nitrate acid of mercury. An ancient officer of marine, whom M. P. Pelletan sent to me, had, on the left side of his nose, a cancerous, bosselated, sanious plate of a reddish color, which had been there over two years. Every kind of topical and internal treatment had been resorted to in this case. Slight cauterizations with the liquid above mentioned, effected a cure in the space of six weeks. The father of a young physician, in the environs of Nantes, had, on the lobule of his nose, one of those plates, (plaques,) which completely disappeared under the influence of four similar cauterizations; and I could at the present time relate a great number of similar facts. To succeed in such cases, it becomes necessary to clean the tumor carefully of all the crusts with which it may be covered. I then besmear it with butter in the evening and morning, with the view of softening this incrustation the night before each cauterization. All the crusts thus besmeared easily allow afterwards of being detached, and we thus have the altered plate immediately naked before us. I then take a small pinch of lint which has been saturated with the liquid above mentioned, to touch in every part, and even a little beyond it, the surface to be destroyed. The pain which it produces at first is sometimes quite severe. The parts touched by the acid become white, and excite occasionally a slight exudation of blood; there is then formed upon the surface a yellowish crust, which may be detached at the expiration of four or five days, in order to renew the same operation, and so on to the end of the cure. From four to six or eight cauterizations applied in this manner are generally sufficient. If the plate should be composed of an agglomeration of sebaceous follicles, the cone of nitrate of silver introduced to the bottom of each one of them would succeed equally well, and would even be

more suitable. When it is thicker, hard, and of a certain breadth, the *zinc paste* appears to me to be preferable. Having vivified (*avivé*) the altered surface, by means of ammonia or a blister, and taken care to do so effectually, which the nature of the tissue in these cases sometimes renders difficult, we apply over it a plate of zinc paste, (*pâte de zinc*) from one to three lines thick, in such a manner that this plate goes half a line beyond the entire circumference of the tumor; we then fix it here by means of a suitable containing bandage, taking care that nothing is disturbed, at least during twenty-four hours. All the degenerated tissue is transformed, by means of this caustic, into an eschar, which falling off at the end of six to twelve days, leaves in its place a wound whose aspect soon announces that cicatrization is about to commence, and whose bottom dries up and quickly becomes a sufficiently regular portion of the surface of the nose. Moreover it is important, when we employ zinc paste, potash, or butter of antimony on the nose, not to penetrate too deeply, and to remember that in this region the teguments are very thin, and that it would be easy to come down upon the bones or to the cartilages, so as to produce a necrosis there, as M. Champion has seen in two instances. Upon the supposition that the tumor had much more thickness than breadth, we might perhaps attack it with the bistoury rather than by caustics. We should succeed by this method if, after the tumor was removed, the lips of the wound could be readily brought together, either by simple tractions, or after having detached them on their deep-seated surface to the extent of some lines all round. Should the loss of substance be too considerable to do this with facility, we should have nothing more to do than to recur to the resources of rhinoplasty, or be contented with a cicatrization by second intention. This last practice would have to be adopted for the operations performed on the sides of the nose, and between the forehead and the wings of this organ; and in this case there could be no other than advantages follow from cauterizing at the first the whole bottom of the wound. At the root of the nose anaplastic processes present sufficient chances of success to authorize their employment. At the point or the alæ, they would become still more important, since cicatrization there by second intention is almost always followed by considerable deformity.

III. *Elephantine Tumors*.—The nose, in certain individuals, is sometimes transformed into a reddish mass of a violet color, at other times simply greyish and covered with bumps, and which has given rise to the expression of *mushroom* or *potato* nose. This alteration, which seems to be no other than an extraordinary development of the natural integuments of the part, may acquire so great a degree of extension that there results from it upon the nose an actual tumor, very analogous as to its nature to elephantine tumors of the scrotum. These tumors have sometimes been seen to acquire a weight of several pounds. As they do not cause any pain, rarely ulcerate, or undergo any transformation of a bad character; and as it is also almost impossible to get rid of them by other than by surgical means, patients do not usually pay any attention to them until they have arrived at a very advanced stage of their development. Imbert de Lonnes (*Opér. Faite*, le 16 Brumaire, an VII, in 8°, 8 pages,) has published a very remarkable exam-

of one. A former mayor of Angouleme had on his nose a bosselated tumor of the weight of about two pounds, and which hung down as far as the chin, hermetically closing up the nostrils and the mouth. This man, in order to breathe and speak, was obliged to bend down with his head forwards. He could neither eat or sleep except by raising up his tumor, which he suspended by means of a sling fixed to his night-cap,—a ligature, which had been made trial of, caused such pain that it had to be laid aside. Imbert then decided upon extirpating it, and was obliged to lay bare the whole surface of the nose, which operation required twenty-two minutes. No accident took place, and the patient got perfectly well, preserving a nose which was not very greatly deformed.

Analogous facts have been related by the Academy of Surgery, (*Mémoires*, t. III., p. 511,) and the work of Hey contains some which are not less interesting. The subject, however, had no longer been spoken of by practitioners, when M. Dalrimple (*The Med. Quarterly Review; Gaz. Méd.*, 1834, p. 136,) communicated new facts in relation to it. In his first patient, who was fifty-four years of age, the tumor hung down upon the mouth and reached nearly as far as the chin; the surgeon removed it on the 4th of August, 1826, and the wound healed up in a month without leaving any disagreeable deformity. Another patient operated upon in the same manner, got well in as short a space of time. In performing this operation in 1831, in a man who was more than eighty years of age, M. Dalrimple was obliged to remove a tumor almost as voluminous as that which has been described and figured by Imbert de Lonnes. No indications of a return have shown themselves since. In these different cases, it is important during the dissection of the parts, that the surgeon should place one of his fingers in the nostril, in order to direct the action of the bistoury, and to guard himself better against every perforation. As for the rest, the removal of maggots, cancers, and elephantine tumors of the nose does not differ from that of diseases of the same kind which are seen in any other region. It would be the same also with erectile tumors: Maréchal (*Archiv. Gén. de Méd.*, t. XXIII., p. 149) successfully extirpated one which was of the size of a nutmeg, and which was situated at the tip of the nose.

IV. I will nevertheless remark, that on this last point it is important to recollect the cul-de-sac which lies under it, and that the lobule of the nose is hollow behind, and generally furnished with walls that have but little thickness. So that in fact this organization renders their perforation almost inevitable when the cutting instrument is applied to it, or the slightest caustic of any activity. From whence there results a species of hole which is readily transformed into a *fistula*, and which being once cicatrized in its periphery, cannot afterwards be closed but with an extreme degree of difficulty. I have met with two patients in whom the end of the nose had been excised in order to destroy a cancer, and in whom this fistula resisted every kind of attempt directed against it. A young girl, who in falling from her bed cut her lip and the lobule of the nose, in striking her face against a chamber-pot, which she broke, rapidly got well of all her wounds, with the exception of a point of the lobule of the nose, which remained fistulous. I was not however enabled to cure this

fistula, until after having abraded it by means of the bistoury, and reunited its borders by a point of the twisted suture. The attempt at reunion by every different kind of bandage or plaster, cauterizations with the nitrate of silver, nitrate acid of mercury, and the head of a probe heated to a white heat, which had been made trial of during the space of two months, had completely failed. We should have, therefore, in such cases, to resort to abrasion and the suture, provided the suspension or the elevation of the end of the nose by means of adhesive plasters or any kind of bandage and cauterizations well applied, did not answer at first.

B. *Tumors of the Septum*, (cloison.)—The septum of the nose in front of the cartilage which divides the nares into two passages, is quite frequently the seat of tumors, to which the moderns only have paid any serious attention. These tumors sometimes concrete, but most usually liquid, establish themselves between the two tegumentary layers which are continuous from the exterior to the interior to line the nasal fossæ. An English surgeon, M. Fleming, (*Dublin Journal*, 1833; *Gaz. Méd.*, 1833, p. 798,) has frequently met with tumors purely sanguineous in this part, a disease which is sufficiently common in that country, says the author, in consequence of the mode of attack which the English so often make use of in their pugilistic combats. M. Cloquet (*Journ. Hebd.*, No. 91, p. 544, 1830) appears to have observed abscesses here very frequently, and M. A. Bérard (*Arch. Gén. de Méd.*, 3e série, t. I., p. 408) has published two cases similar to those of M. Cloquet. I have also on my part seen in the substance of the sub-septum of the nose, collections of blood or of pus and masses that were semi-concrete, and, as it were, tuberculous. Whether liquid or concrete, the tumor, nevertheless, in such instances, protrudes on each side into the openings of the nose. If it is a deposit of blood from external violence, time and topical resolvents will generally remove it in the space of fifteen days or a month. In case of failure, we should have at a subsequent period to treat them by incision, or in the manner I have said of céphalématomata. Abscesses should be laid open as soon as possible upon one side, and freely, if the same sac projected to the right and left; upon two sides, on the contrary, if there were two abscesses there in place of one. We should proceed also in the same manner if the abscesses were simply tuberculous, except that we should then have to apply afterwards the nitrate of silver throughout the whole extent of the morbid cavity. For tumors that were purely concrete, or where there was an alteration of the anterior border of the cartilage of the septum narium, we should have to proceed in another way. In describing the sub-septum of the nose, Bichat indicates the possibility of an *operation*, which up to the present time had existed only as a project, but which M. Rigal has performed. In backing on the median line, the cartilages of the lobule leave between them a small groove, perceptible even through the skin, which enables us to separate them apart by means of the instrument, and to penetrate as far as to the septum narium without opening into those cavities. A cancerous tumor developed under the anterior nasal spine, and which had gradually extended in front, downwards, and on the side, as far as to the alæ of the nose, had nevertheless scarcely altered the tegumentary layer.

Two incisions, united in front and passing around behind and outward in such manner as to represent a  $\lambda$  reversed, having surrounded the cancer laterally, it became easy, by means of a transverse incision, to detach it below from the upper lip, then by doubling back the two lips of the first wound, to arrive at the cartilage of the septum, to excise its anterior border and remove the entire morbid mass. The sides of the division were afterwards brought together, and the cure was uninterrupted by any accident, unless it was that the progress of the cicatrization, by drawing the tissues backwards, had ultimately flattened a little the alæ and the top of the nose.

## § II.—Occlusion and Contraction of the Nares.

In consequence of confluent small-pox, syphilitic or other inflammations, rhinoplasty itself, and all lesions in fact which may alter the form of the nose, the anterior opening of this organ is liable to become closed up, or at least to be narrowed to so great a degree as to interfere very materially with respiration.

A. *Ordinary processes.*—We remedy such inconveniences by three different modes: 1. Dilatation; 2. Incision; 3. Excision. It is rare that dilatation alone suffices; it is besides applicable only in cases of narrowing, and not of entire closure of the passages. Incision in its turn almost always requires dilatation to be associated with it. Excision becomes useful only where tubercles or morbid projections are to be removed. Should the opening be merely narrowed we incise it by numerous excentric cuts, and to greater or less depth, according to the extent of the disease. When it is entirely closed up a narrow bistoury should then be plunged in at the place which it usually occupies. We make in this manner an antero-posterior incision, the borders of which it would be afterwards advisable, as I think, to divide on two or three points of their length. To prevent the wound or small wounds from reuniting and destroying the effect of the operation, it is recommended to keep them open and separated apart by means of a tent of lint or linen. As we must by every means in our power force them to cicatrize separately, and in the position we have first given them, it appears to me that we might attain our object better by means of a piece of sheet lead rolled up in the shape of a ring, and to which we could moreover give such form as we desired, than by means of the dilating bodies generally employed. It is, however, an operation too simple to require that I should dwell any longer upon it. Nor have I found that it has been as difficult as has generally been said, to give to the opening of the nares again in this manner, their necessary dimensions. A young girl whom I received into the hospital of La Pitié in 1833, and in whom the openings of the nose had been reduced to a small aperture, in consequence of an eczematous affection, which had been for a long time cured, was submitted by me to the excentric incision of the cicatrix, afterwards to dilatation by means of a large canula of gum elastic, and recovered perfectly well. I saw her again more than a year after, and there was not the slightest tendency to any contraction of the anterior opening of the nares.

B. *New method*.—If the incision or the simple excision should not appear to present all the chances of success desirable, there might perhaps be a mode of arriving at something more certain, by adopting the following course. The surgeon, provided with a straight bistoury, would circumscribe the whole of the deformed cicatrix, by surrounding its base on the border of the former opening, and very near the skin of the nose. Afterwards dissecting this circle as if to isolate it, as it were, from the internal surface of the organ, and in such manner, that after having removed the entire arcade of morbid tissue we should have in its place a prismoidal groove, there would be nothing more to do than to bring together the two borders of this new wound by a sufficient number of points of suture. We should thus procure immediate reunion by means of an operation, which leaving no wound, nor any traumatic surface in the interior, would not expose to a new contraction. It would be, moreover, applying to the openings of the nose, what I have proposed as one of the best methods for contractions of the mouth. I will add, that by following this method, it would be rendered almost unnecessary, to keep a canula or any foreign body in the nose during the cicatrization of the wound. Having treated of the manner of reconstructing the sub-septum and the alæ of the nose under the chapter on Anaplasty, I do not propose to recur to it again at this time. I will only remark, that having seen in 1838 the person formerly operated upon by M. Gensoul and previously by Dupuytren, I was enabled to ascertain that the flap borrowed from the upper lip and fixed to the lobule of the nose, in order to construct the fibro-cartilaginous septum, which a lupus had destroyed in this patient, had maintained itself in a sufficiently satisfactory condition. The only inconvenience which results from it is a slight depression of the lobule of the nose and too great a projection of the sub-septum (or columna) below. This fact proves then incontestably, as do those also which have been published by M. Liston, that the sub-septum of the nose may be perfectly well re-established by means of an elongated flap taken from the middle of the upper lip. (See notes on Anaplasty, Vol. I.)

C. *Rhinoraphy*, or the simple suture of a slit, either in the alæ or in any other part of the nose, as practised with success by M. Roux, and also by myself, being no other than a modification of rhinoplasty, or subject to the same rules as cheiloraphy, does not require to be described separately.

## ARTICLE II.—LACHRYMAL PASSAGES (VOIES).

The *nasal canal*, formed on the inside by the posterior border of the ascending process of the superior maxillary bone, and the anterior third of the os unguis, and altogether below by a small lamella of the inferior turbinated bone; outwards, forwards, and backwards, by the maxillary bone, and its turbinated bone, and then in a slight degree by the ensiform process (crochet) of the os unguis; having a length of three to five lines; circular at the middle part; a little wider from before backward than transversely, on its upper portion; and terminating below by an orifice which flares open in the manner of a funnel,—possesses in reality no solidity except in

the antero-internal third of its circumference : from whence it follows that in attempting to pass an instrument (traverser) through it, it is very easy to break its other walls, and penetrate either into the nasal fossæ or the maxillary sinus. The lachrymal groove (*la gouttière lacrymale*,—i. e. gutter,) which seems to prolong its internal wall as far as to the corresponding orbital process of the frontal bone, and which is more and more superficial in proportion as we ascend into the orbit, presents on the other hand inferiorly two lips, which are easily recognized ; one anterior belonging to the ascending process, the other posterior and formed by the outer crest of the *os unguis*. The fibro-mucous membrane, which lines the nasal canal, and to which it is but slightly adherent, becomes much stronger and more complicated in the gutter, where it takes the name of the *lachrymal sac*. Here the direct tendon of the orbicularis muscle crosses its anterior face at a right angle, as if to divide it into two halves, the one superior upon which this tendon sends off a fibrous expansion, known under the name of reflected tendon, the other inferior and lined outwardly by cellular tissue, and which has boundaries which it is exceedingly important should be understood. This last mentioned portion [of the lachrymal sac] is always confined within that triangular space, which is bounded above by the direct tendon, below by the border (*rebord*) of the orbit, and outwardly by a vertical line which would fall upon the outer side of the *caruncula lachrymalis*. It is, moreover, covered only by some fleshy fibres, and by lamellar tissue, and the teguments of the nasal angle of the eye. Being but feebly supported by the surrounding tissues, it readily yields to the influence of causes which have a tendency to dilate it, and thus frequently becomes the seat of tumor and of *fistula lachrymalis*.

The apertures for absorbing the *tears*, (*puncta lachrymalia*), and which are surrounded by a small elastic and dense, but not cartilaginous circle, have a direction perfectly vertical, but form a very distinct angle (*coude*) where they become continuous with the lachrymal duct, properly so called. This last, which traverses only the inner fifth of the free borders of the eyelids, is situated more especially upon their posterior portion. Being formed by the mucous membrane only, it is exceedingly thin, and superficial in its postero-superior half ; while the remainder of its circumference, making part of the body of the eyelids, presents in front and below a far greater degree of solidity of texture. Now, it is this anatomical arrangement which obliges us to enter perpendicularly at first, in order to rest afterwards much more in a direction towards the eyelid than the eye, when we catheterize the lachrymal ducts themselves. At their entrance into the sac these ducts are sometimes separated by a small projection or sort of spur ; frequently also, they unite together by one opening. Taken together, the lachrymal sac and nasal canal present a double curve, which has some resemblance to that of an Italic *S*, that is to say, that the first [the sac] is slightly convex posteriorly and inwards, while the second [the nasal canal] is so in the contrary direction ; so that in order to perform catheterism on the upper eyelid, we must take care while the probe is traversing the sac, to incline its lower extremity rather forwards and outwards, than in an opposite direction, and that in order to traverse the nasal canal, it is

better, on the contrary, to push the instrument from before backwards, and from without inwards. As every one must have remarked, the axis of the nasal canal in its relations with the supra-orbital projection, presents very numerous modifications; as does also the depth to which we have to go to find it in the orbit. In persons in whom the root of the nose is flattened and broad (large) it appears to be thrown outwards, and perceptibly contracted. When on the contrary, the ossa nasi (les os carrés) are very nearly approximated to each other at their inner surface, we cannot reach it except by coming much nearer to the median line. When the frontal bone is very projecting, and the maxillary bone very prominent, the nasal canal (conduit des larmes)\* is found at a very considerable distance from the posterior surface of the direct tendon, while in persons who have the canine fossa very deep, and the forehead depressed, it appears to come out a slight distance beyond this tendon. The species of valve or diaphragm which contracts its lower extremity, is usually perforated only in its posterior half. Its orifice [i. e., the outlet of the nasal canal into the nostril, T.] is situated at the depth of six or eight lines in the nose, at the apex of a cavity which is bounded in front by the base of the ascending process of the os maxillare, and inward by the concave surface of the inferior turbinated bone. As this cavity is prolonged a little more in front of than posteriorly to the lachrymal valve, it happens sometimes that catheterism at this lower part (cathéterisme inférieur) is very difficult if the surgeon is not aware of this arrangement. The length of the nasal canal itself rarely exceeds from six to eight lines. Demours has met with *bridles* in the nasal canal. M. Taillefer (*Thèse*, Paris,) describes a membranous duplicature [repli] which was situated in its upper third, and the free border of which, directed downwards, sent off several filaments, which attached it to another point in the same canal; so that if a probe had been passed from below upwards it would evidently have been arrested by this anomaly. Different authors whose observations are given by Sandifort, relate examples of small calculi found in the lachrymal passages; similar instances also have been since related by Schmucker, Eller, Walther, Krimer, M. Levanier, M. Graefe, and formerly by Kern. More than this, the nasal canal has been found entirely closed; Morgagni gives an instance where both were closed, [en relate un exemple double,] and Jurine as well as Dupuytren, have both met with one. The *lachrymal passages* may be the seat of lesions in each of their three principal divisions, viz., in the sac, the ducts and the puncta lachrymalia, and also in the nasal canal.

### § I.—*The Puncta and their Ducts.*

A. The puncta and lachrymal ducts may be *obliterated*. Small pox, purulent ophthalmia, a long protracted blepharitis, wounds and ulcers on the internal portion of the eyelids, are the principal sources of this alteration. The tears being then no longer able to penetrate

\* As our author a few lines above applies *conduit lacrymal* to the lachrymal or tear ducts properly so called, this inadvertence might lead to ambiguity, but for the subsequent rectification it receives by his admirable anatomical precision. T.

into the sac, run over upon the cheek, so that the eye is moistened as if weeping, (lave,) while there is present at the same time a peculiar dryness in the corresponding nostril. We may then have present epiphora, an alteration, or even the disappearance of the punctum lachrymale, and ulcerous, purulent, atrophied or hypertrophied condition of the border of the eyelids, and afterwards of the nose, with the absence of all kind of tumor or fistula lachrymalis.

Gunz states that he has seen a case of this kind in which however the tears found their way into the nasal canal by means of porosities which were recognizable to the naked eye. This kind of alteration, which has not been taken notice of but by a few persons, is worthy of additional researches and appears to be altogether incurable. J. L. Petit and Pellier, who pretend to have reconstructed an obliterated lachrymal duct, by passing a sharp pointed probe through the place it had occupied, were certainly deceived by some of the circumstances of the case. Whatever in fact may be the instrument made use of to fray out a passage so delicate as the lachrymal duct, and whatever may be the kind of seton afterwards employed in this passage to keep it open permanently, we may rest assured that the tears will not take that course, and that it will shut up as soon as the dilating body is removed. Such operations therefore are perfectly useless; it is better in such cases to imitate Bosche (Malgaigne, *Thèse de Concours*, 1835,) and cauterize the puncta in order to close them permanently, should there be any trace of them left. If they were merely contracted or only obstructed by some thick matter, all that could be done would be to clean out the passage by means of Anel's syringe and injections. In such cases A. Petit (Peiffer, *Thèses de Paris*, No. 222, 1830) and Lèveillé (*Traduct. de Scarpa*, t. I., p. 84,) are of opinion that we ought to establish an opening to the lachrymal sac by means of loss of substance between the caruncula and eyelid, at the place which Pouteau had selected. But it is not probable that such an opening would keep open for any considerable time, nor that it would afford any particular relief. An artificial opening by excision to the duct itself, upon the inner side of the punctum obliterated, would do much better. It continued open in two patients upon whom I had operated with another object in view.

**B. Fistulas of the Duct.**—Should any ulcer or lesion happen to perforate the lachrymal duct on the side towards the eye, there might result from it a particular form of fistula which is one of the most difficult to heal. A thread of gold or silk, or small cord of catgut, passed in the manner of a seton through the injured duct, from the punctum as far as the lachrymal sac, is the only remedy that art possesses against an infirmity of this kind, unless we should have recourse to opening the nasal canal on the inside of the eyelids. I have moreover, in two cases, seen the tears pass through the new route, that is, by the accidental aperture into the duct, in the same way as through the natural punctum, without any inconveniences resulting therefrom, and I doubt if fistula of the puncta lachrymalia in reality constitutes a disease.

**C. Cysts.**—Sometimes also one of the puncta of the lachrymal duct becomes dilated in the manner of a cyst. So at least J. L. Petit,

Boyer and Pellier state that they have seen it. As the tumor causes no pain, it should be treated by resolvents, so long as it shall not have acquired such size as to render it too troublesome. It would moreover be unnecessary to extirpate it in order to obtain a radical cure; as it would be equally certain to disappear by laying it open and cauterizing its interior. Formerly they used to expect that there would result from this an obliteration of the duct and probably also an incurable epiphora. But I shall have occasion farther on to refer to some facts which will have a tendency to allay the fears of surgeons on this subject.

D. *Polypi*.—The lachrymal puncta are also liable to a species of small vegetations or kind of polypi. Demours (*Précis des Maladies des Yeux*, 1821) speaks of a small fungus which protruded from the lower lachrymal punctum, and which he cured by excision followed by cauterization.

### § II.—*Lachrymal Tumors and Fistulæ Lachrymales.*

The lachrymal tumor is rarely if ever a dangerous disease: it incommodes by the crustaceous condition which it keeps up on the border of the eyelids, causing thus a predisposition to ophthalmia, the sensation of dryness which it produces in the nostrils, the purulent matters which it forces to flow back upon the eye, and by the deformity it causes in the great angle; but it compromises neither life nor the general health, nor even the physiological condition of the globe of the eye, properly so called. It may however ultimately, and it is thus in fact that it most frequently terminates, give rise to acute inflammation in the sac, then in the neighboring tissues, or it may become transformed into an internal anchylops, and finally produce a fistula lachrymalis. This inflammation of the lachrymal sac sometimes reaches the periosteum of the neighboring bones, as of the os unguis (lachrymal bone), for example, or the maxillary or ethmoid, or even the frontal and nasal bone, so as to denude them and cause necrosis or caries of the inner wall of the lachrymal sac or nasal canal. I have seen this inflammation extend itself to almost the entire side of the face, and terminate in the manner of phlegmonous erysipelas in the eyelids and at the root of the nose. Happily these are but exceptions, and the lachrymal tumor rarely gives rise to any other than a very circumscribed abscess before it becomes transformed into fistula.

*Fistula lachrymalis* therefore is but one of the consequences of the tumor of the same name. It appears to me however that this fistula may in some instances be formed without having been preceded by tumor of the sac.

We may conceive for example, and I have now instances in point, that a loss of substance, either in consequence of certain operations, or we will suppose, from wounds, contusions, burns, or ulcerations, might destroy a part of the free portion of the lachrymal sac in such manner as to establish there an actual fistula. I believe, moreover, to have in two instances seen a fistula establish itself from the exterior to the interior, after the anchylops had already made its way out through the skin. However this may be, fistula lachrymalis is an ulcer

which communicates by an accidental opening with some point in the track of the tears. We should, therefore, by that definition, have to examine fistulas of the lachrymal ducts, those of the nasal canal, and fistulas of the lachrymal sac. But these last only have hitherto been the subject of special attention, and as to the others I have made a few allusions to them farther back. Fistulas of the lachrymal sac are sometimes *internal*, that is, that they may open into the middle meatus of the nasal fossæ, into the sinus maxillare or in the direction of the eye posteriorly to the palpebral commissure; but that they are almost always *external*. Under the last circumstances also, the cutaneous orifice, which, in ninety-eight times out of one hundred, is found in front of the lachrymal sac, may nevertheless occupy another position. I have in one case seen it on the prominence of the cheek, and in another case near the ala of the nose; a sinuous track of more than an inch thus separated the external from the internal orifice of the fistula. Ordinarily there is but one of these orifices; but sometimes the skin at the great angle of the eye is, as it were, cribbled with them. Frequently this orifice makes no projection, but even appears to be a little depressed; at other times it is found situated on the top of a kind of sac which is flabby or flattened, or occasionally more or less distended. It is not an uncommon thing to see it afterwards surrounded with fungosities, and presenting the aspect of an ichorous ulcer of bad character. In fact, nothing is so simple as the mechanism of a lachrymal fistula. The sac, for a long time distended in the state of tumor, is worn through (*s'éraïlle*) or ulcerates; the inflammation extends sometimes suddenly, at other times by imperceptible degrees, to the neighboring layers, and an abscess is formed. Whether this abscess opens of itself or is opened by art, it nevertheless puts the cavity of the sac in communication with the atmosphere through the skin. If the ulceration makes its way directly to the skin, the fistula is direct or complete; if it spreads (*fuse*) or the contrary, either between the periosteum and bones, or among the other organic layers in the direction of the nostril, it is indirect and incomplete, and becomes an exception. We can readily understand how the os unguis, which is so thin and fragile, and the osseous plates with which this bone articulates, may ultimately become necrosed and carious, when we reflect upon their relations with such seats of inflammation and suppuration. As the treatment of fistulas in practice has generally been confounded with that of lachrymal tumors, I propose, in this place, to examine under one head the therapeutic of these two forms of the same disease. The treatment of lachrymal tumor and fistula has, at every epoch, occupied the attention of practitioners; after having been for a great number of ages almost entirely pharmaceutical, it became almost exclusively mechanical from the moment when the functions of the lachrymal apparatus became well understood. At the present day opinion seems to have taken another direction. Recognizing that the lachrymal tumor and fistula were the result of an inflamed condition of the nasal canal or lachrymal sac, practitioners finally asked themselves the question, whether the treatment of inflammation, modified according to the individual, and the peculiarities of the diseased region, ought not, in a great number of cases, to have the preference

over mechanical means. At the present time, therefore, before proceeding to surgical remedies, these affections are to be treated by resources of another character.

*A. Topical Applications and General Treatment.*—The first object of the surgeon ought to be to ascertain the causes, whether individual or constitutional, of the tumor or fistula. If the patient under treatment were affected with syphilis, scrofula, or scurvy, it would be necessary, before doing any thing else, to bring about the cure of these general derangements of the economy. It is to be understood, also, that tumors of the nasal passages, orbit or maxillary sinus, as well as any other disease in those regions, ought to be previously destroyed, should they have been the point of departure of the disease in question. If the affection should have developed itself in consequence of any disease of the skin, of the lips, or the Schneiderian membrane, it would also be necessary to commence by removing them. In those instances, quite common, of lachrymal tumor and fistula, which originate, as it has appeared to me, from an eczema of the upper lip and the encrusted condition of the opening of the nostrils, I have made use, with advantage, of a pomade composed of a gros of white precipitate to an ounce of lard, and sometimes also of another pomade containing eight grains of nitrate of silver to an ounce of lard. The parts affected are to be rubbed morning and evening with one of these pomades, taking care to remove the crusts previously, by means of emollient cataplasms. If, on the other hand, the case in question is one that comes under those tumors and fistulas originating from disease of the eyelids, I employ, before all other things, the means proper to cure this last. Influenced by the idea of an inflammation of the mucous membrane of the lachrymal passages, all the school of Beer maintain that we should treat it by debilitating remedies. It is for this reason that M. Mackenzie eulogizes general bleeding, leeches, and water, as a topical application and for the regimen, in the acute, and even also in the chronic state of the disease. M. Lawrence, still more specific, prescribes leeches to the internal angle of the eye and upon the tumor, and compresses wet with cold water as a resolvent.

The credit of this practice might equally well be ascribed to Demours, for this surgeon was in the habit of treating the diseased condition of the lachrymal passages by leeches and regimen; every where he speaks of having cured lachrymal tumors and fistulas of long duration without an operation. Emollients, procrastination, and cold lotions (*les lotions froides*—means of course, cold water,) were his favorite remedies, and we see by the consultations described in his great work, that it was the method also of his father. It is from not having been *au courant* on this subject with the history of the science, that some surgeons among us between 1820 and 1830, supposed that they were the authors of it. In fact, it goes still much farther back; for Manget, in 1693, wrote that fumigations by the nose and general treatment did exceedingly well with lachrymal fistula. Heister, who like Platner was aware that inflammation was the immediate source of this disease, and who compared the affections of the lachrymal passages to those of the urethra, treated them also by injections, bleeding, blisters, and regimen, which are almost

always sufficient he says, if there be not yet either ulceration or caries in the great angle. It is to be added, however, that before M. Gama, M. Guillaume, M. Paris, and some other military surgeons, (*Mém. de Médec. et de Chir. Milit.*, etc., t. XIV—XVI.) but few persons in France, except Demours, thought of combating lachrymal tumor by means of antiphlogistic remedies.

*Practice of the author.*—One consideration naturally suggests itself here ; that is, to know to what extent debilitating measures are allowable under such circumstances. A regimen which is quite rigid, with some general bleedings, repeated application of eight, ten, fifteen, twenty or thirty leeches to the temple, mastoid processes or nasal angle, emollient cataplasms, cold topical applications, injections, or aqueous fumigations, continued for two, three, four, and six months, do not at first succeed but in a very small number of cases ; afterwards this practice manifestly becomes more painful and dangerous than most of the surgical remedies now employed ; from whence it follows that we should be wrong in according too much confidence to this kind of medication, and that we ought to consider well before adopting it. There are some lachrymal fistulas, moreover, which we have it in our power to cure without an operation, by means of a treatment better regulated, and less calculated to disturb the constitution. Thus, unless there are particular indications to the contrary, I would advise neither general bleeding, nor leeches to the temples, or behind the ears, nor a seton to the nape, which Fabricius de Hilden (*Bibl. de Bonet*, p. 394, 397,) recommends, nor a plaster of tartar emetic as eulogized by M. Weller, nor internal remedies ; but I willingly employ, and have often done so with success, some of these remedies applied as near as possible to the parts diseased. From six to ten leeches on the track of the nasal canal and lachrymal sac, renewed three to four times in the space of a month, may be useful, if there be remaining a certain degree of inflammation and heat in these parts ; the same remark applies to the fumigation of Manget or Louis, and to topical emollients. After this first period it would be necessary to recur, as was already the practice in the time of Rhazes, (Guy de Chauliac, *Traité* IV., doct. II., chap. 2.) to the application of friction to the tumor or collyria between the eyelids. Upon the tumor we may apply either mercurial ointment, that of hydriodate of potash or ioduret of lead, and also temporary blisters. As collyria, we no longer employ the melange, lauded by Rhazes, but may make use with advantage of a lotion of sulphate of zinc, lime-water, a solution of nitrate of silver, and in fact any solvent or styptic collyrium. Introduced into the lacus lachrymalis, (le lac lacrymal,) these liquids are absorbed there by the puncta lachrymalia, and thus tend to destroy the inflammation which constitutes the obstacle to the course of the tears. Le Dran, who had already employed liquid collyria under this form, and Mackenzie, who has substituted them for the injections of Anel, have obtained with them decided success ; I have myself often used them and with very excellent effects. Nevertheless we must not deceive ourselves in respect to their efficacy. Though in the space of one year I have seen four women cured of lachrymal tumor and fistula under the treatment I have just described, I ought to add also that most of the other cases of the same

kind to which I had before been witness, have since returned to me, and convinced me that the cure was not permanent. We succeed by this treatment then only as an exception, and not eight times out of ten, as some persons at the present day have ventured to affirm; but what justifies trials of this kind is, that the surgical means at present known, in spite of their number, nevertheless still leave the treatment of lachrymal tumor and fistula very imperfect and meagre. In truth, the methods which have been from time to time eulogized for the cure of fistula and lachrymal tumor, having almost exclusively for their object the removal of a presumed obstruction, which is sometimes wanting, and which is only in fact the result of another disease, could not have otherwise than failed frequently.

These means, moreover, are so diversified, that in order to appreciate them properly, it is important to separate them into several classes. Thus, among those who have proposed them, some like Méjean and Anel, by means of catheterism and injections had no other object than the cleansing out of the nasal canal by penetrating through the lachrymal ducts; others, namely, Lecat, J. L. Petit, Cabanis, Palucci, Foubert, Jurine, Desault, Pamard and Scarpa, had especially in view the dilatation of this canal. Many persons recurring to the idea of Heister, have supposed it more rational to employ in those parts injections of various kinds, or to apply caustics, in the same way as is done for contractions of the urethra. A fourth group in fine, embrace the methods which, like those of Woolhouse, Hunter, Warner, and many others, were designed to establish a new route for the course of the tears. Among these methods there is a considerable number which would deserve to be consigned to entire oblivion; but as they are still employed by some practitioners, I think it advisable to make a brief review of the greater portion of them. In conclusion, I would divide the surgical treatment of lachrymal tumor and fistula, into four general methods, namely: the method of catheterism and injections, that of dilatation, thirdly, cauterization, and lastly, the method for establishing an artificial lachrymal passage.

*B. Catheterism and Injections.*—To believe Bianchi and Signorette, Stenon, Valsalva, and Stahl, a veterinary surgeon mentioned by Morgagni, must have already made an attempt to penetrate the tear ducts, by means of very fine styles (tiges) more or less adapted to their object, until Anel attracted attention to this subject in 1716. Portal, (*Hist. de l'Anat. et de la Chir.*, etc., t. IV., p. 486,) in fact, asserts that we find the germ of this principle in Cajus Julius, Plato, Septalius and Duret; but it is easy to perceive that Bianchi was deceived, and that Manget, in reality, is the only one who effected the passage of these ducts before the time of Anel. According to its partisans, catheterism of the lachrymal passages is called for, in tumors, fistula, simple obstruction, more or less complete obliteration, partial or general contraction, ulcerations and chronic inflammation of the lachrymal ducts, sac and puncta, as well as of the nasal canal. We may have occasion for it in order to introduce threads, tents, different kinds of meches, injections, and medicated liquids, and we may perform it either through the eyelids or the nares. This method presents two principal varieties: with it in fact we propose sometimes to clear out, sometimes to modify the interior of the diseased

ducts : in one, the object of the surgeon is evidently mechanical ; in the other, it is more physiological.

1. *The mechanical variety.*—*a. Process of Anel.*—Anel had two modes of treating affections of the lachrymal passages : sometimes he endeavored to clear them out (*les désobstruer*) by means of a very fine probe, at other times by the aid of injections that were either detersive or impregnated with some other medicated property.

1. *Injections.*—To introduce injections, Anel devised a small syringe of the capacity of two to three gros, terminating in a very fine syphon, to the point of which was adjusted a copper pipe much finer still. The patient was made to sit down fronting a well-lighted window. With the left hand for the left eye, and the right hand on the contrary for the right, the surgeon gently depresses the lower eyelid and inclines its free border forward. With his other hand he takes the syringe, introduces its point perpendicularly into the orifice of the tear duct, causes it to penetrate in this direction to the depth of about a line ; then placing it horizontally, he inserts the little copper syphon to the extent of two or three lines, then presses his thumb upon the ring which is at the posterior extremity of the piston, and cautiously forces forward the medicated liquid into the lachrymal sac. The inferior lachrymal punctum is preferred for this purpose, because the operation by that of the upper eyelid, would in fact be less convenient and less certain. Should the operator prefer placing himself behind the patient, he would depress the lid of the right eye with his right hand, and the lid of the left eye with his left hand.

He might also, were he not ambidexter, employ the same hand for both sides, by taking care to place himself in front for one of the eyes and behind for the other. At first the patient bears these manipulations rather badly : they produce in fact, in some instances, a good deal of irritation. It is only after having gone through with them for several days successively that he gets accustomed to them, and that they become as simple as they do trifling in pain. Saint-Yves and Heister also had recourse to injections, but they made them through the fistula. W. Blizard (*Transact. Phil.*, t. LXX. ; *Journ. de Méd.*, 1781, t. LXXIII.) influenced like his predecessors, by the principle of clearing out the passage, proposed that mercury should be used in the injections.

2. *Catheterism.*—When the injection does not arrive at all, or but in very small quantities into the nasal fossæ, Anel recommends that we should immediately have recourse to the use of the probe. The operator, if to act upon the superior lachrymal duct, places himself behind the patient, gently reverses the eyelid outwards and upwards, with the left hand for the right eye and with the right hand for the left eye, seizes the probe with the other hand in the manner of a writing pen, perpendicularly applies the blunt point of the instrument on the lachrymal punctum, afterwards inclines its other extremity outwards and upwards, as if to carry it towards the external orbitar process, cautiously advances it in, draws with his other hand the nasal portion of the lid inwards and towards the internal orbitar process, as if to give him a vertical direction, immediately pushes in the probe in this last mentioned direction, taking care when meeting with the slightest obstacle, to raise it up, or

incline it a little either in front or outwards or backwards or inwards, in order to force it in fine to penetrate into the corresponding nostril; after which he withdraws it to have recourse again to the injections. The introduction of this probe is a delicate operation, which cannot be otherwise than fatiguing to the patient. It demands on the part of the surgeon an exact knowledge of the arrangement of the parts. The slightest fold, whether natural or morbid, is sufficient to arrest the instrument, which, in consequence of its small size and flexibility, is in reality incapable of overcoming the least degree of resistance. I will add that in every point of view it is a useless operation, for the lachrymal tumor and fistula are scarcely ever owing to a complete obliteration of the nasal canal. Moreover, if matters that would yield to the action of the probe could be the cause, they might be displaced full as well by simple pressure made upon the tumor. This pressure, which Richter recommends to be made from above downwards, and acting in the manner of injections forced into the urethra, would evidently have more efficacy than Anel's probe. Nevertheless the operation of catheterism continues to be performed and described, because, as will be seen farther on, some practitioners have applied it to the radical cure of fistula lachrymalis itself.

*b. Process of Laforest.*—Perceiving that injections and catheterism by the method of Anel were sometimes very difficult, and believing them moreover to be of unquestionable utility, Laforest and Allouel, nearly about the same time, proposed to penetrate into the lachrymal passages through the nares. To attain his object, Laforest had constructed small plain sounds curved into an arc, and catheters (algæ) of the same form, which were conical and open at their apex and terminated at their base by an ear (pavillon) furnished with a small lateral ring, designed to fix the instrument upon the side of the nose in the interval between the dressings. The plain sound, inserted from below upwards into the nasal canal, was intended to clear it out. After having removed this, Laforest replaced it by the hollow sound, which enabled him to inject by means of a small syringe, the liquids adapted to the nature of the disease. Laforest's sounds in our times have been modified by a number of surgeons. M. Gensoul has given them much more length and a curvature exactly shaped to that of the nasal canal. Those of M. S. Pirondi are of metal at their extremities, and gum elastic in the middle. Those of M. Serre differ only in their curvature from the catheters of M. Gensoul. With this last form of the instruments, catheterism of the nasal canal is in reality very simple, however little we may be practised in it, and modern practitioners are in my opinion wrong in so entirely neglecting to employ it.

*II. Physiological variety.*—The method of Laforest, like that of Anel, has been but seldom used for the purpose designed by the author; but other surgeons have endeavored to combine it with certain stages of the operation for fistula lachrymalis. Heister and Le Dran had already become satisfied that in a large number of cases, injections in the character of topical resolvents might render every kind of operation unnecessary. Briot, for example, as M. Champion also does, was still employing the process of Laforest with the most decidedly advantageous results. These injections,

either from above or from below, are in reality remedies that deserve to be retained. It is in fact obvious, that by directing medicated liquids upon the seat of the evil, we must sometimes succeed in dispersing it; only that the question arises whether by processes still more simple, we should not be enabled to attain the same object, and whether substances introduced through the nose by means of fumigations, as Manget proposed, or by inhalation, would not in the same manner pass into the syphon of the tears, as Monlac and Louis affirm they have caused them to do with success.

C. *Dilatation*.—When the lachrymal tumor has become ulcerated, or does not yield to the processes of Anel, Laforest, Louis and Le Dran, nor to general and local antiphlogistic measures, nor to antiscorbutic and anti-syphilitic treatment, &c., it is admitted that it cannot be cured except by the operation, properly so called. It is not to be forgotten, however, that Maitrejean has seen two fistulas of the most serious character at the great angle of the eye get well spontaneously; that Demours rarely treated it by the cutting instrument; that the ancients, with their extensive battery (*tout leur échafaudage*) of escharotics, styptics and caustics, occasionally made some cures; in fine, that in our own times we have seen cases recover which had been treated only by local bleedings and the soothing regimen. This remark is so much the more important, as we may perceive thereby that all the different methods have occasionally succeeded in effecting a cure of fistula lachrymalis. As this disease is of a character to get well sometimes spontaneously, it is not therefore surprising that compression, already extolled by Avicenna, and for which J. Fabricius, de La Vauguyon, and Schmidt, constructed bandages of considerable ingenuity, and that tents of lint besmeared with an ointment of greater or less activity, and that leeches and emollient cataplasms, should, in a number of instances, have promoted the cure. In November, 1831, an adult man was sent to me at La Pitié by Dr. Grenier, in order to be operated upon for a lachrymal fistula, the existence of which, now of several months' duration, could be satisfactorily established. After procuring a canula, the fistula was found closed up, and when I saw the patient again, at the expiration of three months, the cure continued perfect. If leeches, or any other kind of medication had been employed, the cure would undoubtedly have been attributed to them. In 1836, I saw two similar results at the hospital of La Charité, and analogous facts have been related by MM. Moztehan, Caucanas, (*Journ. Compl. des Sc. Méd.*, t. XXXII.) Demours, and Moulinié, (*Bull. Méd. de Bourdeaux*, 1833, p. 138,) as well as by F. de Hilden, (Bonet, *Corps. de Méd.*, 394—397,) and Fichet de Flechy, (*Observ. Méd. Chir.*, p. 258.) Dilatation comprises two modifications: in one we act on the natural passages; the other, on the contrary, exacts an artificial opening for the introduction of the dilating body. Each of these methods, moreover, includes quite a considerable number of processes.

I. *Dilatation by the Natural Passages*.—*a. Process of Méjean*.—Méjean, perceiving that the employment of injections, and the clearing out of the lachrymal passages by Anel's probe, afforded only temporary relief, proposed to apply to the nasal canal the treatment by dilatation, which had been so long in use for contractions of

the urethra. By means of a fine probe, having an eye at its upper extremity to receive a thread, this author traverses the parts in the manner of Anel, and endeavors to insert the blunt end of the probe upon its arrival near the wall of the nares, into the groove or opening of the canula, (*sonde cannelée*), which has been introduced at the bottom of the lower passage, (i. e. by the nose,) in order to meet the probe, and to draw it through together with the thread attached to it; forming afterwards a noose with this species of seton he unites its two extremities around a pin, which is fixed into the cap or hair of the patient. At the expiration of one or two days, two strands (*brins*) of lint, folded double, are attached to the nasal extremity of this thread, in order to form a *meche*, which is besmeared with cerate or some other medicated pomade, and has another thread fastened to its free extremity. The *meche* is then drawn from below upwards through the nose, and as far as to the upper part of the lachrymal sac. Each day it is to be removed, and its size increased by adding one strand more of lint. To remove it we have recourse to the thread which retains it in the nose, and which between the dressings is to be kept fixed upon the cheek by means of a bit of court-plaster, (*mouche de taffetas*.)

By this process the treatment requires from two to three, four or six months, and the cure obtained is rarely permanent. Out of twenty patients thus treated there are rarely more than three or four in whom the disease does not reappear at the expiration of a few months. The method of Méjean, moreover, presents two difficulties which are not always easy to be overcome. The probe often gets stopped in the lachrymal sac, and does not reach the nasal canal until after long and fatiguing trials. Except we are much practised in the operation, we have generally considerable difficulty in bringing it under the inferior turbinated bone, into relation with the groove or eye of the canula, or in getting hold of it in any manner so as to bring it out.

*b. Process of Palluci.*—Palluci suggested that by introducing a small gold flexible canula (*sonde creuse*) instead of Méjean's probe, we might be enabled to pass through this canula a portion of catgut so fine, that the patient would drive it out in sneezing, when it could afterwards be made use of to conduct in the same direction a thread for the purposes designed in the process of Méjean. But it is obvious that this modification complicates the operation of the physician of Montpellier in place of simplifying it, and that it must be more easy to make our way through the lachrymal passages by means of a probe than with a canula.

*c. Process of Cabanis.*—Cabanis, a physician of Geneva, has suggested an instrument designed for seizing with greater facility Méjean's probe in the lower meatus, and which is composed of two palettes made so as to slide upon each other. Being perforated with holes which traverse the entire thickness of the upper palette, but go only to a certain depth in the body of the lower one, this instrument is first introduced below the inferior turbinated bone, (*cornet maxillaire*.) By means of skillfully combined movements the probe is arrested in one of the holes of the two palettes united, by which it is soon securely embraced, (*exactement pincé*.) Cabanis also recommends, after having brought Méjean's thread through the

nose, that its extremity should be attached to the end of a flexible sound covered with gold-beater's skin, in order to conduct this sound with certainty through the lower meatus into the nasal canal, after the manner of Laforest.

*d. M. Bermond* of Bordeaux, who revived this suggestion in 1825 and in 1827, has very justly remarked, that in order to apply it, all that is required is to bring the conducting thread of Méjean to the outside by any mode whatever. Inasmuch as the instrument of Cabanis is not indispensable, and removes only a part of the inconvenience of the process of Méjean, and as the introduction of the probe and thread through the superior lachrymal punctum, counterbalances the advantages which might result from it for the subsequent introduction of a sound, in the manner of Laforest, surgeons have not adopted these modifications.

*e. Process of Guérin.*—Guérin of Lyons, having remarked that a simple thread left to remain in the superior lachrymal duct, excoriates and sometimes lacerates its palpebral orifice, recommended to bring Méjean's tent as high up as this punctum. Desgranges, who, like Guérin, finds it more convenient to reach the extremity of the probe through the nose by means of a small blunt erigne, than with the canula, or the palettes of Cabanis, adopted this suggestion, which Care on his part has more recently endeavored to render popular.

*f.* The process of this last physician, according to what he has stated to me and from what I have seen in the practice of M. Bougon, consists in passing from below upwards or from above downwards, by means of the instruments of Méjean, a meche of raw silk, composed of three, four or six brands, in order that the same may, while traversing through the superior lachrymal ducts and puncture, dilate them as it proceeds. When it has been passed from below upwards, one of its extremities is afterwards fastened to the forehead of the patient, or in the contrary case, upon the side of the nose. With the remainder of the meche we form a sort of peloton which is to be attached in the hair. A. Dubois appears to have several times followed this method, which I have also made trial of in two instances, and which differs in nothing from that of Guérin. Care's meche, by dilating the sound part only, without acting directly upon the diseased point of the organs it traverses, deforms and paralyzes the lachrymal puncta and their ducts. As I have not understood that experience has pronounced in its favor, I do not see any inducement to make any more trials with it.

II. *Dilatation by an artificial opening.*—When in order to dilate the nasal canal we penetrate by an artificial opening, we sometimes make use of temporary dilating bodies, and at other times of dilating bodies that are left to remain in the lachrymal passages.

*Temporary dilatation.*—For this kind of dilatation, surgeons make use of meches of lint, bougies, or metallic bodies.

*a. Meches and Setons.*—1. *Process of J. L. Petit.*—Petit was the first who endeavored to inculcate, that in fistula lachrymalis we ought to exert ourselves to re-establish the natural passage of the tears, much rather than to create a new one for them. His method may be considered as the source of all those that are employed at the

present day. An assistant placed behind the patient draws the temporal angle of the eyelids outwards, in order to stretch the parts; the operator then directs the point of a bistoury into the sac below the direct tendon of the orbicularis muscle, and makes at the great angle of the eye an incision of about six lines; glides in the place of this instrument a canulated sound, which he pushes with more or less force into the nose, through the nasal canal, and makes use of it to introduce a tent or conical bougie of wax, the upper extremity of which should be more or less dilated and supported by a thread. The operation is then terminated. The bougie is to be renewed or at least cleaned every day before putting it in its place, until the canal no longer furnishes any evidence of suppuration, that is to say during two, three, four, five, or six months. At a subsequent period, J. L. Petit thought that he could make a substitute for the canulated sound, by making a groove near the back and on the anterior surface of the bistoury, which would answer to direct the extremity of a blunt probe; but as a special bistoury would be required for each side, practitioners have generally paid no attention to this pretended improvement.

2. *Process of Monro.*—The approbation which the method of Petit first received did not prevent some surgeons from recognizing its defects. According to Monro it would be imprudent to open the sac without supporting its external or anterior wall. It is for this reason he proposes to introduce through the inferior lachrymal duct, a small sound, in order to distend it and to enable him to open it without wounding its posterior wall. Monro also recommends we should force through the nasal canal, by means of a shoemaker's awl, an instrument already mentioned by Guy de Chauliac, rather than with a sound; that by means of the scissors we should prolong the opening upwardly at the risk of dividing the direct tendon, and that in place of the bougie of Petit, we should make use of a small tent of lint or catgut. His precepts have been neglected. The wounding of the lachrymal sac posteriorly, besides being easy to avoid by the ordinary process, cannot involve any danger, whatever M. Rougier may say of it, while that of the tendon of the orbicularis is in itself a serious accident. The employment of an awl would expose us too much to be misled, and to the making of false routes, to render it possible that it can ever be preferred to the blunt-pointed probe and the canulated sound.

3. *Process of Pouteau.*—Introduced from above downwards, the bougie ultimately produces in the great angle an ulcer whose borders are reversed inwardly, and which sometimes leaves as a consequence a cicatrix which is greatly depressed. Pouteau having in vain tried the method of Méjean in a young lady, and not daring to propose the incision of the sac in the manner of Petit, decided upon passing his bistoury between the lower palpebral border and the caruncula lachrymalis, in such manner as to penetrate into the nasal canal without interfering with the skin. There resulted from it, says the author, only a slight ecchymosis, which itself was owing to his having made the incision too narrow. With the exception of one of the Pelliers, but few persons, however, have thought it advisable to imitate his example, though it has since been lauded by Leveillé, and

that M. Bouchet has employed it in one instance with success. The apprehension has been, that the conjunctiva would be too much irritated. Moreover, the inconvenience which Pouteau has proposed to remedy is reduced to so trifling an affair in the modern processes, that at the present day it is scarcely regarded.

4. *Process of Lecat*.—Lecat after having incised the sac in the manner of Petit, made use of meches of lint, which he introduced through the nasal canal from above downwards, by means of a cat-gut, a fine bougie, or Méjean's probe. In this respect he is the first who has endeavored to combine the method of Méjean with that of Petit; but as his meche also had a tendency to produce the reversion of the borders of the wound, so much dreaded, very little attention has been paid to the precepts that he has endeavored to lay down.

5. *Process of Canolle*, (*Mémoire sur l'état actuel de la Chir.*, par Montfalcon, p. 118, 1816.)—M. Canolle, when he thinks a seton indispensable, inserts a treble cord of a violin (*chanterelle*) which has been oiled, through the opening of the fistula, as far as into the nasal fossæ. When the patient feels an itching at the back part of his mouth, the surgeon explores this cavity, seizes the foreign body with the forceps and brings it outside; he then introduces a small bougie into the nostril corresponding to the side upon which the fistula is, until he has arrived behind the wall of the palate; he then withdraws this also with the forceps and proceeds to tie it to the extremity of the cord. He immediately withdraws the bougie through the nostril, then follows the cord; it is separated from the bougie, and a thread attached to its extremity. The cord drawn through the opening of the fistula, brings with it into the lachrymal passages the thread to which the seton is attached.

6. *Process of Desault*.—To obviate as much as possible the inconveniences of the preceding processes, Desault gives to the incision of the sac only two or three lines of extent. A canulated sound is immediately made use of to clear out the narrowed canal; a probe or a whitlow sound is then put in its place. A small silver canula, from twelve to fifteen lines long, conical in shape, and having a ring on the side of its pavilion, is brought from above downwards, as far as into the nose, by means of the probe which forms its axis or guide, and which is immediately afterwards withdrawn. The thread is then made to descend into it, and the patient forces out its extremity by making efforts to blow his nose; after which the operation differs in no respect from that of Méjean.

7. *Modification of Boyer*.—In order to be certain of making as much thread as we desire descend through the canula of Desault, we may, after the manner of Boyer, make use of a small probe of three to four inches long, bifurcated below, and terminated above by a ring; then afterwards, in order to extract this thread, have recourse to the little erigne of Deschamps, the dressing forceps, or merely make the patient blow his nose. If neither of these suffice we abandon it in the nose, when in almost every instance the mucosities ultimately draw its extremity through at the end of from twelve to twenty-four hours. In the contrary case, injections driven with a certain degree of force through the opening of the lachrymal sac, would not fail to expel it downwards.

8. *Process of Pamard*.—Pamard and Giraud, embarrassed by the difficulties of extracting the thread according to the method of Desault, devised, almost about the same time, an improvement which many surgeons of our day still make use of. It is a small elastic stem or watch-spring, terminated by a blunt point (*bouton*) and presenting an eye at its other extremity. The head of this spring is inserted into the canula of Desault. Having arrived under the inferior turbinated bone, its elasticity naturally carries it sometimes towards the opening of the nares, and sometimes under the lobule of the nose, where it is easy to secure it either with the finger or the dressing forceps. Nevertheless, when the spring is not well tempered, and even sometimes when it is perfectly constructed, its extremity cannot be disengaged from the inferior meatus of the nasal fossæ but with a considerable degree of difficulty.

9. *Process of Jurine*.—In order to leave as little deformity as possible in the angle of the eye, Jurine performed the operation with a small trochar of gold, and whose canula is pierced near its point. It is plunged in as far as the nose. After having withdrawn the stilet we introduce Pamard's spring; in other respects we conform to the rules established farther back. If, in spite of its apparent simplicity, this process has not been adopted, it is, because, in reality, it is more painful and less easy than many others. It will always be more rational to open the lachrymal sac with a bistoury than with a trochar. And then the process of Pamard is preferable to that of Jurine.

10. *Process of Fournier*.—An ingenious modification of the operation of Petit, and which I am astonished to see omitted in our modern treatises, is the one which has been proposed by M. Fournier of Lempde. This physician proposes we should attach a small shot or grain of lead to the conducting thread of Méjean; drawn down by its weight this shot traverses the canula of Desault, and falls of its own accord into the interior of the nose, from whence the patient readily expels it by merely taking the precaution to incline his head forward. G. Pellier had already, with the same purpose, made use of the end of a leaden sound.

11. *Process of Janson*.—M. Janson (*Compte Rendu de la Prat. Chir. de l'Hôtel Dieu de Lyon*, 1822, p. 51) anoints the lachrymal sac and clears out the nasal canal with a whitlow sound, whose notch enables him to direct a catgut into the nasal cavities; he then proceeds to seek for this last with a blunt-pointed erigne; on the second or third day he substitutes for it a silk thread, which serves to conduct from below upwards a small meche of cotton, the size of which is gradually augmented until the cure is completed. This process has the advantage of leaving nothing to appear outside but the portion of thread of flesh color, which, from the great angle of the eye, is concealed under the head-dress of the patient. "It would be difficult for me," says the author, "to relate the number of fistulas operated upon in this manner; but what we may assert as indisputable is the superiority that may be accorded to it over every other method whatever."

12. The editors of Sabatier have also remarked that the combination of the methods of Méjean and Petit may be effected without the

array of instruments brought into use by Desault, Pamard, Boyer, and M. Roux. What need is there, in fact, of introducing successively into the nasal canal, a sound, a probe, a canula, and then a watch-spring? Why not be content to place the thread in the conducting instrument, and to glide this last into the nose as soon as the *lachrymal sac* is incised? The species of spring acting in the canula in such manner as to transform itself into a hook, which was proposed in 1806 by M. Benezech, in order to extract Méjean's probe more readily, would have no advantage over most of the other means which have been hitherto pointed out, and consequently does not require any farther notice.

13. *Process of Jourdan*.—Apprehensive that the whole extent of the evil might not be laid bare, and desirous of avoiding the cicatrix of the integuments, M. Jourdan, imitating Pouteau, has proposed to open the lachrymal sac throughout its whole length, behind the internal commissure of the eyelids within the caruncula. M. Vésigné is doubtless wrong in asserting that it would be generally impossible to conform to this advice; but it is nevertheless true that the process of M. Jourdan offers no advantage over the others, that it would incur the risk of wounding the internal extremity of the lachrymal ducts and of dividing the muscle of Horner, and that it would present more difficulties than any of those that are in daily use.

14. *Process of Manec*.—Should the introduction of the conducting thread of Méjean still present some difficulties, we might readily surmount them by means of the instrument devised by M. Manec. It is a sort of spear-pointed sound, introduced through the nose from below, upwards into the nasal canal, and as far as to the palpebral angle. The spear point is then made to pierce through the anterior wall of the lachrymal sac, and its eye is made use of to draw the thread through the nostrils. What will hinder this ingenious modification from being generally adopted, is the difficulty that many practitioners experience in penetrating with any instrument whatever, into the nasal canal through the inferior meatus.

b. *Bougies and Cylinders*.—1. *Process of Scarpa*.—While in France they endeavored to give popularity to the seton of Méjean, the physicians of Germany, Italy, and England, limited themselves to a modification of the method of J. L. Petit. Scarpa, having no more apprehension of dividing the direct tendon than his pupil, M. Luzardi (*Journal de Méd. de Nancy*, 1825, p. 234) has since had, advises that we should insert into the lachrymal sac and nasal canal, which he first cleanses by means of meches besmeared with red precipitate or nitrate of silver, a leaden pin or a species of conical nail, terminated above by a flattened head, and more or less inclined downwards, in order that it may accommodate itself to the form of the inner angle of the eye. This pin (*clou*), which B. Bell kept in for eight to nine weeks only, ought to be withdrawn from time to time to be cleansed, and reintroduced immediately afterwards. During the first weeks the surgeon himself attends to this duty, and injects with warm water into the lachrymal passages before replacing there the metallic stem, which Scarpa calls the tear conductor. At a later period the patient has no need of any person to attend to the dressing. As soon as the tears flow freely into the nose without

any obstacle, and that the pin ceases to be covered with purulent matter, we may, in fact, dispense with its employment. Nevertheless, it is advisable to continue it for some weeks longer, in order to be more certain of preventing a return. "There are some patients," says Scarpa, "who are so little annoyed by it that they cheerfully carry it all their lives."

2. I have seen at Paris *Dubois* and *M. Bougon*, successfully use a leaden pin, which only differs from that of Scarpa in having its upper extremity merely curved in the form of a hook, in place of being flattened like the head of a nail. After having employed both I give the preference to Scarpa's pin, to which I allow a length only of ten to twelve lines, and to whose point I give a strong curve, while others prefer to have this end in an enlarged base.

3. *Process of Ware*.—There are those who prefer a silver pin to the tent that I have just spoken of. Ware, for example, has given rise to the adoption by many surgeons in England of a silver pin, which in other respects is in almost every point similar to that of Scarpa. After having lauded the canula of Wathen, Ware has substituted for it the pin in question, and maintains that it conducts the tears into the nose by a sort of attraction. We thus perceive that the process of Scarpa was entirely modelled upon that of Ware. Demours, before having adopted the gold canula, employed a silver pin sixteen lines in length and curved into a hook above.

4. *Process of Larrey*.—M. Larrey in his turn substitutes for these instruments a portion of catgut, three to six lines in length, fixed on a plate or sort of button made of taffeta of flesh color, in such a manner that the whole has considerable resemblance to the little candle, known under the name of *veilleuse*. This instrument is removed, cleansed, and reapplied every morning. Adherent by its head upon the skin, and requiring only a small aperture, it is scarcely perceptible at the great angle of the eye and causes no annoyance to the patient.

5. *Beer, Scarpa, and Weller*, eulogise also small bougies or catgut, but under another form.

D. *Permanent Dilatation*.—*a. Permanent Canula*.—According to Louis, Foubert had proposed to place permanently into the nasal canal a silver canula about an inch in length, conical in shape, and terminating inferiorly in the form of a spoon. Bell and Richter have also mentioned this canula on the authority of La Faye, who himself mentions canulas of gold, silver, or lead, left in the canal as a common practice, and without citing Foubert. But Louis having formally censured it, it was scarcely any longer spoken of by the surgeons of that time in spite of the efforts of G. Pellier, who in 1783, gave himself out as the inventor of it, relating in his work facts which plead strongly in its favor. Pellier moreover had modified it very ingeniously. His, which is of less length than that of Foubert, was made to terminate above in a border, and presented in the middle another border; so that being once introduced it became impossible for it to ascend or descend. It does not appear moreover, that it has ever fallen into complete oblivion. Distel says that one of his patients carried one for more than fifteen years, and that he took one of tin from another which had been in place for forty years. I perceive

also by a thesis sustained in 1802, that at the Hospital of Strasbourg no other method than this had been pursued for a long period. M. Marchal, the author of this thesis, furnishes nine cases which are altogether of a conclusive character. In Germany it was employed also by Himly and Reisinger; but it had been almost forgotten in the schools of Paris when Dupuytren recalled the attention of practitioners to it, by giving it only one border instead of two. This border, concave inwards, where it presents a circular groove, is arranged in such manner, that in order to withdraw the canula if any accident requires it, it is sufficient to introduce into its interior the beak of an elastic forceps terminated by two little hooks, whose points turned outwards readily draw it from below upwards. I will however add, that if Ansiaux is to be believed, these modifications of the canula of Pellier had been proposed by Giraud even at the Hotel Dieu, ten years before Dupuytren used them, and that they were adopted at Liege in the year 1806. In place of presenting a border in the middle, that of M. Brachet has the second one at the lower extremity. M. Taddei has approached much nearer than any other person to the views of Pellier, by recommending that we should place a slight border below its upper third. M. Grenier, who considers that the canula only escapes in consequence of its ceasing to be pressed upon in a sufficient degree by the nasal canal, has proposed to construct one which may be contracted when it is compressed, and which on the contrary acquires a larger calibre, like a spring, as soon as it is left to itself. In the year 1756, Tillolig considered that it would be advisable to withdraw it through the nose at the expiration of a few months; while in 1781, Wathen proposed to fix a thread to its upper extremity in order to hinder it from descending, and M. Nicault recommends that we should make use of a cone composed of several plates of sheet lead rolled around each other. Other modifications still have been made to the canula of Pellier. Some persons have proposed to perforate it with holes, the better to prevent its slipping. M. Bourjot finds that of Dupuytren too long, and makes the objection to it, that it ultimately rests upon the floor of the nasal fossæ. M. Blondlot is in favor of a bellied canula, in order to dilate the canal gradually and imperceptibly. The one that I employ terminates in a blunt point, and not like the beak of a pen, which would expose it too much to the risk of chafing the wall of the nasal canal or perforating the bones; but practice teaches us that the form of the instrument is not a matter of importance in these cases.

*b. To introduce the canula* we may, after the manner of Dupuytren, make use of a steel, silver or gold stilet, a sort of lever bent almost into a right angle, the lower portion of which, adapted to the canula, is bounded by a shoulder more or less prominent, and the handle of which, while it is more or less flattened, has a length of from two to three inches. As soon as the canula has penetrated the little wound, we fix it in this point by means of the nail of the forefinger or thumb, during which the stilet is withdrawn. The patient is then recommended to breathe out with force, and if the air is driven through the angle of the eye, the operation is well performed.

A bit of plaster or taffeta keeps the wound united over the canula, in such manner that its cicatrization frequently is completed as soon

as the following day. Ansiaux asserts that before introducing the canula, it is advisable to clear out the nasal canal with a sound or a probe. An incision having been made into the sac, he introduces a blunt probe through it as far down as into the nose, and afterwards makes use of this probe as a stilet to conduct the canula into the nasal canal, the cleansing of which by means of the proper topical applications he also recommends, as Delpech (*Clin. Chir.*, t. II., p. 433) had recommended it to be by cauterization, a practice which is likewise followed by MM. Bouchet and Lusardi, (*Journ. Méd. de Nancy*, 1825, p. 235.) M. Blandino has revived at Paris the modification of the Belgian surgeon, which M. Taddei had also believed himself the author of. M. Cloquet, who does not leave the canula permanently in, until after having made use of tents during the space of some days, and M. Chaumet and M. Bérard, who previously dilate the canal by means of bougies or catguts, gradually increased in size, have also in these respects, gone farther than Ansiaux. To penetrate upon the inner side of the eyelids, as M. Vèsigné wishes, with a view of avoiding a cicatrix, would be truly superfluous, and this assuredly is not a case for conforming to the precept of Pouteau. With a view of rendering the operation still more simple and prompt, M. Daniel has contrived a sort of trochar or stilet, terminated in a lancet point, to carry the canula into the nasal sac in such manner that the operation is thereby reduced to one stage. This instrument, which the author has shown to me, and which is applicable to the most simple cases, would, like that of Jurine, possess the inconvenience of not making a sufficiently extensive incision of the skin, of fraying out with too much facility a false route into the substance of the walls of the canal, and of not permitting the employment of means rendered necessary by a variety of circumstances difficult to be determined beforehand.

c. The canula may be of *silver, gold or platina*; the important point is, that it should possess some degree of solidity, and that it cannot be easily injured. Its size and length ought to vary according to the subject. It is necessary that it should adapt itself as nicely as possible to the nasal canal, and that it should pass a little beyond the lower extremity of that passage. Consequently we ought to recall to mind, that in an adult this passage is from five to eight lines in length, and from one to two lines in breadth. It is also advisable that it should be slightly concave posteriorly, and on its inner side, and that its point, if it is cut in the shape of a pen, should pass beyond the antero-external rather than the nasal wall of the canal which it occupies.

d. *To adapt its proportions to the stature of the patient at the different epochs of life*, M. Grenier has proposed a method which, as it appears to me, attains this object with sufficient precision, viz., that the length of the nasal canal is to be estimated by a line drawn from the point where the incision is made in the great angle to the superior depression of the ala of the nose, at the union of the lower border of the nasal bone with the ascending process of the superior maxillary bone.

e. *Appreciation.*—The use of the canula having been adopted to great extent in France, requires in this place that I should examine

with some care its importance and its inconveniences. Many objections have been made against it. It is, they assert, a foreign body which, by its presence, causes irritation to the system, produces cephalalgia and pains in the face and in the nose, erysipelatous inflammations, phlegmons abscesses and ulceration in the great angle of the eye. Frequently it makes its way upwards under the integuments, and M. Darcet relates twenty-seven cases where its extraction became indispensable. In other cases it falls into the nasal fossæ, and the operation is, so to speak, abortive. All these inconveniences were pointed out by M. Bouchet in 1816, and presented in a correct point of view, in Italy, by M. Pl. Portal. Like Delpech, (*Clin. Chir.*, t. II., p. 433,) M. Ouvrard, (*Méd. Chir.*, p. 265,) Bécclard, (*Clin. des Hôp.*, t. IV., p. 106,) and MM. Cloquet, Bourjot and Laugier, (Diday, *Thèse de Concours*, Janvier, 1839,) I have seen it pass through into the vault of the palate. It is even said that, in one instance, it fell into the trachea, and that it became necessary to have recourse to tracheotomy; but this is a statement that requires confirmation. The canula may also get involved in the sinus maxillare, (Ouvrard, *Méd. Chir.* 265,) or into the substance of the alveolar border.

Mucosities and powders that many persons put in their nose, ultimately obstruct it and close up its orifices. Finally, when we are obliged to extract it, we find ourselves under the necessity of performing an operation more difficult than that of the fistula lachrymalis itself. If the instrument glides between the maxillary bone and the soft parts of the face, instead of passing into the nasal canal, as I have seen it do in two instances, it will cause symptoms more or less serious, without having the slightest beneficial effect upon the fistula properly so called. The same result takes place if we force it into the neighboring sinus, or get its point entangled in the walls of the canal, or if it descends between the bones and the membrane of this passage, or in a word, if it does not exactly follow the natural channel of the tears; it is also clear that a large canula cannot be conducted without danger through a canal which is too narrow, and that if we insert a small one into a very large canal the operation will equally fail of success. In answer to these objections I may reply: it is for the surgeon to be prepared to avoid these different mistakes, or at least when he commits them not to throw the blame upon the operative process. In the other methods it is necessary to renew the dressing every day for several months, and there are none of them that have not equally caused cephalalgia, erysipelas, &c. By the process of Dupuytren some seconds only are required to terminate the operation. The patients are cured almost as soon as they are operated upon; no dressing, and no particular care is necessary; most of the patients immediately after resume their customary occupations without thinking that they carry a canula in the great angle of the eye. We obtain in this manner from twelve to fifteen cures out of twenty cases. A young woman who had the canal so narrow that in order to introduce a canula of very small diameter, I was obliged to employ a very considerable degree of force, got well, however, after a slight degree of cephalalgia, during the space of three days; I was, so to speak, obliged to pierce (*tarauder*)

the canal in order to force in a canula in a young man aged twenty-one years, who, nevertheless, was re-established in his health on the following day ; I kept him at La Pitié, and no accident supervened. The worst that can happen after all is, that we may be obliged to withdraw the canula ; for that purpose we have to find the upper opening of the nasal canal, and to seize hold of the foreign body with a small pair of forceps. When any difficulties are encountered, the stilet of Dupuytren with a double hook, the little hook of M. Cloquet or M. A. Stevens, or better yet, the stilet of Caignou, with a double spur, will readily overcome them. We may also make use of a dissection forceps, one of whose extremities has been made to terminate on its inner side by a small curved point. With one of these instruments, the beak of which is placed in the groove of the border, or equally well below the point of the canula, we readily bring it out by making it follow the route which it had already passed. Up to the present moment I have removed this instrument a great number of times, and the dissection forceps ordinarily have, in most instances, sufficiently answered my purpose. We will remark, moreover, that after the extraction of their canulas, patients are absolutely in the same condition as those who would have been treated during the same lapse of time by the dilating method of Petit, and that many then find themselves radically cured. In two patients the canula, which had descended more than half its length into the nose, could not be seized hold of through the lachrymal sac. An ordinary probe bent into a hook, and directed underneath the inferior turbinated bone, enabled me to extract the canula through the nostril. I have also seen that the canula no longer existed in many persons who believed they still had it, and in whom the fistula or the tumor had become re-established ; for it does in fact often disappear without the patient being aware of it. I have seen surgeons give up the idea of extracting it from the impression, as I myself have been in two instances, that it had become incruited in the bones. If we perceive nothing in the nose, if the canal is free and we strike against nothing above, the canula no longer exists there ; it is useless to look for it. In conclusion, therefore, the canula is not applicable to all cases. When the nasal canal has deviated from its normal direction, has become narrowed in one part or in another in consequence of an exostosis, and its walls are greatly approximated (*resserré*) and indurated ; when it contains ulcers or is the seat of lesions of a still more serious character, it is better to recur to the seton of Méjean, or to some other process better adapted to the case.

Enlightened by a longer experience, I am in fact at the present day obliged to admit that cures by the canula are infinitely less numerous in reality, than I had at first supposed. The error into which many practitioners in this respect have fallen, is owing to the greater number of patients, under the belief that they were cured on the day after the operation, or the day after that, have not afterwards been seen by the surgeon. Desirous to know what had become of them, I have followed them up or caused them to be followed up as much as could be done. I have by this means ascertained that the canula very often ascended into the lachrymal sac during the first four months ; that in a great number of cases, it escaped through the nasal fossæ before

the termination of the second year ; that those that remained in their place, became changed, dissolved and destroyed, to such extent as to be of no value ; that they sometimes break, (Champion, *private correspondence*, 1839,) become sometimes filled up by a sort of blackish colored putty similar to sulphuret of silver, sometimes by stony or sandy concretions ; at other times by lymph, concrete mucus, membranous folds, &c., in such manner that at the end of two or three years, for example, there are few patients who remaining cured preserve it unaltered in the nasal canal ; that it merits in fact almost all the objections that Ware makes against it. It is, moreover, in fine, one of the most uncertain remedies that surgery possesses.

*f. Operative Process.*—Whatever may be the method that is preferred in operating for fistula lachrymalis, there is one stage which at the present day everybody performs nearly in the same manner ; I mean the opening of the sac and the catheterism of the nasal canal. an order to arrive with the greatest certainty possible into the canal, the operator causes the eyelids to be stretched by recommending to the assistant to draw them towards the temple. With the forefinger corresponding with the diseased side, he seeks in the great angle the anterior lip of the lachrymal groove. After having forced out by slight pressure the mucosities (*l'empâtement*) of this part, should any exist, he provides himself in his other hand with a straight, solid and narrow bistoury, the point of which he directs behind the angle of the forefinger in order to plunge it obliquely inwards, backwards and downwards. Having thus arrived in the sac, he immediately raises up the handle of the instrument towards the top of the eyebrow, (*la tête du sourcil*,) in order to descend perpendicularly into the nasal canal. He then takes a stilett armed with the canula, if he wishes to follow the method of Foubert ; a canulated sound or a probe, if he proposes to imitate Petit or Desault, and directs the extremity of one of these instruments upon the back or anterior surface of the bistoury in such manner that this last, in coming out, serves as a conductor to the other. When the opening of the fistula is sufficiently large to permit the passage of the canula or sound, the bistoury is not indispensable. In other cases we sometimes comprise the ulcer in the incision, sometimes leave it above, below or to the side ; in other cases we pay no attention to it : if it is surrounded with fungosities and that they are troublesome, we in the first place remove them, and afterwards proceed according to the usual rules. When we wish to penetrate into the nasal canal from below upwards, that is through the nose, the operator holding the sound like a writing pen, with its concavity turned downwards and outwards, introduces it into the nostril to the depth of about an inch : now raising a little the pavillon of the sound, in order that the apex of this instrument may arrive under the inferior turbinated bone and glide upon the nasal wall, he gently draws it forward to the distance of six or eight lines from the opening of the nostril. He then turns its concavity little by little outwards and upwards ; then by an oscillatory movement skilfully managed, he endeavors by feeling about to make its beak penetrate into the orifice of the nasal canal. We thus arrive without any very great degree of difficulty as high up as to the angle of the eye or even into the lachrymal sac. Force is never required in these cases. Re-

sistance can happen only from the bad direction given to the instrument or some anatomical peculiarities. In inclining the sound too much downwards, upwards, inwards, or outwards, we force its apex against the opposite wall or the periphery of the lower orifice of the canal. The efforts which would then be made, would lead to no result except that of penetrating into the sinus maxillare or orbit, or that of fracturing the inferior turbinated bone, which might be so low down and so strongly incurvated that its free border almost immediately touched the floor or the outer wall of the nose, and thus transformed the lower orifice into an actual canal.

*D. Cauterization.*—Before the channel of the tears was perfectly understood fistula lachrymalis was treated by injections, or by tents or meches of lint introduced into the lachrymal sac, and especially by the application to this part of escharotics and actual caustics. These different methods are already described with a sufficient degree of clearness in the works of the Greek physicians, those of the Arabs, and the authors of the middle ages; only that it was under the same character as the treatment of every other fistulous ulceration. The ignorance which then existed in relation to the anatomical arrangement of the lachrymal passages did not allow them to consider it in other point of view. What Guy de Chauliac says of it proves that Sprengel was deceived in attributing to the ancients the idea of injections of the nasal canal. For more than a century mention had scarcely been made of cauterization, when, in 1822, M. Harveng proposed to create by it a new method of treatment. It was immediately recollected that the nasal canal was somewhat analogous to the urethra, and that its contractions might possibly be submitted to the same kind of medication. At the present day we have two modes of performing cauterization of the lachrymal passages: in one we cause the cauterizing material to be inserted from above downwards, while in the other it is introduced through the nasal fossæ.

*Through the Lachrymal Sac.*—1. *Process of Harveng.*—M. Harveng proposes that after having opened the lachrymal sac, we should introduce through a canula a cautery heated to a white heat, or a meche besmeared with nitrate of silver upon the contracted points of the nasal canal; that we should repeat this one or more times according as may be required; that we should proceed in fact as in the treatment of affections of the urethra by Ducamp. According to M. Vial, whose thesis did not appear until 1824, Mortier, of Lyon, had a long time since promulgated the same idea, which is also attributed to M. Janson, and which M. Taillefer, who also believed himself the author of it, revived in 1827. But it is in reality a mode of treatment which is very ancient, since Heister had already advised to touch the nasal canal with nitrate of silver. Formerly it was adopted by many practitioners. G. de Salicet made use of the green ointment (onguent vert). G. de Chauliac, who prefers the red-hot iron, proposes that we should protect the eye during the operation either by means of a canula, as Alcoatín does, or with paste, as Jésus recommends, or by means of a silver or brass spoon, as practised by Théodore.

2. *Process of Deslandes.*—In the month of May, 1825, M. Des-

landes published another process to effect the same object. An ordinary probe is first introduced into the nasal canal in order to remove any obstructions and to clear out a passage for the caustic-holder; we then glide in its place a second instrument of the same form, having two parallel grooves upon its vertical branch, and which are filled with melted nitrate of silver; this is then turned on its axis in order that the whole circumference of the canal may be cauterized, which finishes the operation.

*Through the Nasal Fossæ.*—I heard in the year 1824, that M. Gensoul, whose labors were published at a subsequent period, dispensed with the opening of the great angle of the eye, and that he applied the nitrate of silver through the lower orifice in the nasal fossæ. M. Bermond, of Bordeaux, in 1825 inserted in the Journals a memoir on the same subject. M. Valat made some mention of it in his thesis, in 1826, and M. Ratier, who, without doubt, was unaware of these different attempts, announced, in 1828, that he hoped to apply the method of Ducamp to the treatment of fistula lachrymalis by penetrating through the lower orifice of the nasal canal.

These different surgeons first proposed to ascertain the place, form and extent of the disease; then to direct the caustic upon it with certainty and ease. In penetrating by the great angle of the eye, as is recommended by Mortier and MM. Harveng and Taillefer, the operation ought not to be attended with any difficulty; by the other method, on the contrary, we must begin by making ourselves familiar with the process of Laforest.

3. *Process of Bermond.*—After having brought the conducting thread of Méjean outside through the natural passages and without any previous incision, M. Bermond without paying any attention to the ulceration of the great angle fixes the thread to the noose of a meche besmeared with wax, which he then draws into the nasal canal in order to receive the impression of the diseased surface (*l'empreinte du mal*). By means of the thread which is attached to the free extremity of this species of bougie, he draws it out through the nose, and puts in its place a tent made of some strands of lint covered with a solid paste, and rendered caustic in the part which is to correspond to the contraction. This process has but one inconvenience, that of requiring the previous introduction of a thread through the lachrymal punctum, duct and sac. We perceive that it is the seton of Méjean rendered caustic; but it might evidently be simplified if, in place of following exactly the natural passages, as the surgeon of Montpellier does, we adopted the precepts of Petit and all the moderns for managing the conducting thread.

4. *Process of Gensoul.*—A small catheter having a curvature exactly similar to that of the passages into which it is to be introduced, is first directed under the inferior turbinated bone and as high up as into the nasal canal, in order to verify the seat of the disease, which is immediately after attacked with a caustic-holder charged with nitrate of silver. More than three hundred patients have been treated in this manner by M. Gensoul, some with the most perfect success, others with only partial results, and many without any advantage at all. In order to give to his stilet and canulas the form that is most convenient, he has taken the exact impression of them by means

of the fusible *alliage* of Darcet. Instruments improved after these principles were shown to me in 1825, by Dr. Blanc, and I was really surprised to see with what facility they could be introduced into the tear duct.

*Appreciation.*—In proposing to cauterize the nasal canal, the surgeons whom I have just named have had no other object in view than to apply the method of Ducamp to the lachrymal passages. It is true, that if cauterization is applicable to the contraction of the urethra, it may also be so for the diseases of the nasal canal; but it appears to me that in the two cases, that neither the action of the medicament that we employ nor the nature of the affection that we propose to destroy, have in all cases been clearly understood. Like those of the urethra, the contractions of the nasal canal are usually kept up by a chronic phlegmasia more or less extended, or more or less accurately circumscribed. In no case could fistula lachrymalis have ever originated from the spasmodic contraction, mentioned by Janin, and to which Richter has given so much importance. Nor does the affection of the eyelids, mentioned by Scarpa, become the source of it except by propagating itself to the lachrymal sac and as far as into the nose, where it causes an engorgement and obstruction of the mucous membrane which may produce an obstacle to the passage of the tears. In other words, lachrymal fistula and tumor depend upon an induration and thickening or a simple chronic phlegmasia of some portion of the lachrymal syphon: but in applying nitrate of silver on organs that have been thus changed, it is not by producing eschars there and in *burning* them that we cure them: but it is by dissipating the inflammation, and by neutralizing and destroying the *stimulus* and the *germ* (epine) which keeps it up, and by bringing about the resolution of the morbid engorgement. It hence follows that nitrate of silver is the only *caustic* which can be reasonably employed, and that those impressions which have so much occupied the attention of practitioners are in a measure useless; that the principal object is to make the caustic arrive in the upper part of the nasal canal when we introduce it from below; and near its lower extremity, on the contrary, when we follow the opposite route, in order that we may make it act upon almost the entire extent of the passage. All the precautions, moreover, that we might take in order to prevent this general action would not attain our purpose. As soon as the nitrate of silver is in contact with the living and moist tissues, it melts and soon diffuses itself in such manner that it is only necessary in the nasal canal to touch a single point to ensure that all the others shall immediately feel its influence. What I here say of cauterization I might apply equally well to dilatation. When a meche or a solid stem is kept either temporarily or permanently in the nasal canal it cannot in my opinion be of any service, except in two ways: 1. By transmitting to the affected surfaces medicated substances that are calculated to destroy the disease; or, 2. By compressing from within outwards the whole circumference of the altered passage. In these cases we cure not by dilating, but in fact by an actual resolvent compression, in the same way as we cure œdema, certain eruptive diseases, erysipelas, &c.

*E. Establishment of a New Canal.*—We find in Aetius and Paul

of Egina, that Archigenes had already pierced through the os unguis with a drill, in order to compel the tears or matters to pass into the nose. Sabor Ebn-Sael, quoted by Rhazes and Avicenna, also eulogizes this resource, which is censured by Mesué. We have every reason to believe that Abulkasem, Roger, and the Alcoatin mentioned by Guy de Chauliac, who all applied the red hot iron on the os unguis, effected the same purpose. Certain it is that their predecessor Celsus speaks of the extirpation of the sac and cauterization of the os unguis as a usual practice, and that G. de Salicet advises when the bone is diseased to cauterize it in such manner as to allow the tears to run into the nose, and that this also was the method of J. de Vigo. Almost entirely forgotten for many centuries, this method was again brought into repute by Woolhouse. It is the only, or almost the only method of treating fistula which was employed up to the time of Petit and Méjean.

1. *Process of Woolhouse.*—The operator makes at the great angle of the eye a semilunar incision which includes the tendon of the orbicularis muscle, opens freely into the lachrymal sac, or even according to Platner or M. Malgaigne extirpates it, and lays bare the os unguis; he immediately fills the wound with lint and does not finish the operation until at the expiration of twenty-four hours, or even two or three days, in order that he may be no longer embarrassed by the blood. A sharp probe is then plunged from above downwards, from without inwards, and slightly from before backwards, as far as into the nasal fossæ, through the lachrymal groove or lower part of the os unguis. A meche of lint or small conical canula is afterwards introduced into this opening in order to prevent its closing; then after its borders are cicatrized and become callous, we introduce a gold canula, which is a little contracted in its middle part, in order that it may not escape either inwards or outwards, and that we may leave it there permanently.

2. *Process of St. Yves.*—Saint-Yves, who had remarked that the process of Woolhouse was almost constantly followed by erosion or reversion of the eyelids, perceived that this inconvenience might be avoided by respecting the tendon of the orbicularis muscle in making the incision at the great angle of the eye. He moreover prefers like Guy de Chauliac to perforate the os unguis with the actual cautery, in order to obtain an actual loss of substance.

3. *Process of Dionis.*—Lacharrière, Dionis, and Wiseman, also recommend the employment of the hot iron, which they apply to the internal wall of the lachrymal sac through a protecting canula made in form of a funnel, the first idea of which funnel appears to go back as far as Alcoatin.

4. *Process of Monro.*—Scobinger, Monro and Boudou made use of a trochar for the perforation of the bone, and had less apprehension than Woolhouse of wounding the ethmoid. Ravaton believed that he could arrive at the same result by means of a curved forceps with which he fractured the os unguis to a considerable extent, followed by a leaden canula. But none of these methods can be followed by a perfect cure, “for very soon after the aperture of the bone fills up,” says Guy de Chauliac, “and nothing can any longer run into or pass off by the nostrils.” Whether the artificial opening

is kept free by means of a meche, or tent, or by a canula analogous to that mentioned by Platner, or a little dilated at its two extremities, like that of Lecat or Pellier, or still shorter or more contracted, like that which Dupuytren used, for example, in the treatment of Ranuncula, or by the hooked forceps of Lamorier, &c., it nevertheless almost immediately afterwards closes up; and it is rare that the contracted canula of Woolhouse keeps a sufficiently long time in its place to render the new passage permanent.

5. *Process of Hunter*.—Hunter believed that he could succeed better by carrying away at once a disk of the os unguis, and the two membranes between which it is placed, in such manner as to form there a circular opening from one to two lines in diameter. To attain this object, he devised two particular instruments: 1. A species of cutting canula similar to the punch of harness makers. 2. A plate of horn or ebony curved in such manner that it could be introduced into the middle passage of the nasal fossæ, and destined to serve as a point d'appui to the punch, while we were acting with the latter from without inwards through the opening of the great angle of the eye. We thus obtain a neat perforation, which only requires to be dressed with a meche of lint to cause its borders to cicatrize and become rounded and callous. As it is almost impossible to apply the nasal plate, and as the perforation with the actual cautery is also accompanied with a loss of substance, without thereby rendering it always successful, no person, with the exception perhaps of MM. Talabère, Rougier, and Janson, who made use of it twelve to fifteen times, and who censures it, have undertaken the operation of Hunter on living man. If however it should be desired to make trial of it, we could easily accomplish it by means of the compass-punch of M. Talrich, or the trephine of M. Montain. The perforated branch of the first of these instruments having been introduced into the meatus, would serve as a point d'appui to the perforating branch, which is applied at the great angle of the eye exactly through the wound of the canal. All that is necessary after, is to press one branch against the other, in order to remove the portion of bone desired without incurring the risk of making a mistake.

6. *Process of Scarpa*.—In our day, Scarpa and others have returned to the employment of the actual cautery, in conformity to the views of St. Yves; that is to say, that after having opened the great angle, as in the simple operation of fistula, without touching, and even at the risk of wounding the direct tendon, they fill the wound with lint, leave it there in this manner during twenty-four hours, or even more, and afterwards direct upon the lower and inner part of the lachrymal sac, a metallic stem heated to a white heat, with which they penetrate into the nose. In order to protect the eye and surrounding soft parts, Scarpa no longer used the simple funnel of Verduc or Dionis, but a conical canula with very thick walls, and which supports a handle several inches long, which is united with its base at a right angle; which canula, figured by Scultetus, and rescued from oblivion by Manowry, is one which Desault also used in practice, and the first idea of which is found in Roger de Palmer or in Alcoatin. Rivard and A. Petit recommend that we should open the sac behind

like Pouteau, and not in front of the eyelid, whether we propose to penetrate into the nasal fossæ, or intend to stop at the canal.

7. *Process of Nicod*.—At a more recent period Nicod has proposed to combine together in this method perforation by means of the trochar, and cauterization by means of the hot iron. In a patient whose nasal canal was entirely wanting, Dupuytren by means of a drill, as recommended by Wathen, made another in the direction of the natural channel, then kept it open by placing a canula there permanently.

8. *Process of M. Laugier*.—Briot having noticed that M. Pécot had, in spite of himself, penetrated in one instance into the antrum highmorianum, and having himself, on another occasion, penetrated through the os unguis into the nasal passage, has furnished the proof that fistula may be cured in this manner, since the affection did not reappear in the two patients whom he mentions. This certainly is better than nothing, but I doubt if, notwithstanding the reasons, and some facts mooted in its favor by M. Laugier, who, transforming this accident into a rule, has proposed to penetrate, at the very first, into the maxillary sinus, and to leave a canula there permanently,—I doubt, I say, if such a method can ever have numerous partisans. Nothing, in fact, proves that the tears, having arrived in the sinus, could make their egress from thence with facility, that they would not produce accidents, or that it would be easy to make an exit for them by piercing the vault of the palate. The perforation of the os unguis would have still fewer inconveniences.

9. *Process of Warner*.—Warner, desirous at all hazards of obtaining a permanent opening for the passage of the tears into the nose, destroyed the os unguis extensively, whether carious or not. In union with the extirpation of the sac, eulogized by Woolhouse, and which M. Jameson has again proposed in our times, the process of Warner has been reproduced by M. Gerdy, since the principal object of this surgeon is to destroy the entire inner wall of the nasal canal.

10. *Appreciation*.—If, as I with so many others have had it in my power to testify, the treatment of lachrymal tumor and fistula by setons, the canula and caustics, will succeed in nine cases out of ten, the process of Woolhouse, already rejected as useless by Marchettis, Solingen, Maitre Jan, and especially by the Nannoni, would in our time no longer be worthy of consideration. So long as it is possible to act on the natural passages, we should, by this hypothesis, be censurable in attempting to create a new one; in the contrary case, it would be more rational to imitate the conduct of Wathen, or pierce through the track of the nasal canal, like Dupuytren, than confine ourselves to the perforation of the os unguis or sinus, as after the manner of Saint-Yves or M. Laugier. Should there be necrosis, we ought then to treat the fistula by one of the other methods, for the disease of the bone requires no other care than it does when situated in any other part of the body. The employment of the actual cautery or chemical escharotics is not without its danger, when they are carried so near the eye: they have, more than in one instance, produced obliteration of the lachrymal ducts, and by this means an incurable epiphora. What would seem to deter still more from the method of Woolhouse is this, that the tears rarely acquire the habit

of falling into the nose, even though the passage which has been opened for them should remain free, (béante.) "As to the mode of cure," says Guy de Chauliac, "by piercing through the nasal channels by means of an awl, it is not approved of by Hében Mesué, and I have not found it effectual, for immediately afterwards the aperture through the bone fills up, and there is nothing which can run through it or flow into the nose;" so that, besides the deformity which it makes at the great angle of the eye, the patient is left with an epiphora, (larmolement, weeping eye or delachrymation,) which is, in most instances, beyond the resources of art; but in my view it is demonstrated, at the present day, that we have very often deceived ourselves on this point, and that we are more than ever justified in still attempting new trials.

*F. Closure of the Canal.*—In the midst of this labyrinth of methods or processes, there is one, perhaps, which has not been examined in a correct point of view; I mean cauterization. Everything authorizes us to believe that practitioners, like Severin, (*Méd. Effic. Exopyrie*, p. 656,) and Scultetus, (*Arsenal de Chir.*, tab. 34, p. 190, 1712,) among others, who had so much confidence in the red hot iron and escharotics, rarely cured fistula lachrymalis but by obliterating the nasal canal. This obliteration, which was proposed by L. Nannoni, was systematized into a method by Delpech, and M. Caffort of Narbonne has written to me that nine patients who were treated in this manner were all cured. A piece of nitrate of silver, as large as a bean, is deposited in the upper part of the canal, while the sac is also cauterized at the embouchure of the lachrymal ducts. The operation is repeated three or four times in the space of twelve days, after which we make use of simple dressing. A hard cord is formed in place of the lachrymal passages, and no epiphora follows! It appears also that Bosche, who cauterized the lachrymal puncta with the the view of shutting them up, had no apprehension from this obliteration; and that M. Malgaigne, like Anel, Gunz, Petit, and Demours, has seen instances where the lachrymal ducts were wanting, and where there was no epiphora produced. If such were the fact, a very simple method might be substituted for all those which have been in vogue up to the present time. The excision of the puncta lachrymalia would be all that would be necessary. I have performed it in two instances, but I can as yet give no statement of the result, except that the tears, notwithstanding, penetrate into the nasal canal, and that I have not been enabled to obliterate in this manner the lachrymal ducts. Cauterization, in the manner of Delpech or M. Caffort, was not successful in the three cases in which I used it. In conclusion, I am of opinion that there remains at the bottom of this subject, a question of physiology and therapeutics which has to be examined.

*G. Anomalies.*—However distended the sac may be, it rarely happens that we are obliged to follow the precept of Boyer, and excise a portion of it, or to have recourse to compression, as Guérin recommends. Cauterization with the nitrate of silver, as advised by Scarpa, would evidently be preferable in the majority of cases.

Excision, however, is a practice which we should be wrong in rejecting absolutely. If it is true that we may in reality dispense with it, it

is also true that it may, in some cases, abridge the period of cure. I have, in four cases, deemed it advisable to recur to it, and have been very well satisfied with it. The tumor, which was half the size of a nut, was of long standing, and with walls very much attenuated. After having laid it open freely from above downwards, and seized one of its sides with the forceps, I removed from it, by one cut of the scissors, an ellipse of four lines in breadth. The cyst, which in these cases is reflected as it were upon the anterior surface of the direct tendon, is only in part formed by the lachrymal sac; so also may we remove a large portion of it without wounding the tendon of the orbicularis muscle. *In place of opening into the great angle* of the eye, the lachrymal tumor has sometimes made its way into the nostril through the os unguis, an example of which is given by Heister. In *internal fistulas*, it is not the re-establishment of the course of tears which is the important point, but the ulcerous affection which is to be arrested or cured. If there should exist a tumor, though the lachrymal ducts and puncta were closed, we should have no other treatment to oppose to them than that of abscesses or chronic inflammations. Compression at first, or resolvents and astringents, and then a cut of the bistoury into the cyst, and the employment of meches or detergent injections, would be all that there was to be done, unless we should incline to leave a canula remaining in the nasal canal. In certain persons the *osseous canal is so small* that we are obliged to employ force, and even a very considerable degree of force, in order to effect the entrance into it either of a canula or any foreign body whatever. The contraction which I have here reference to, is most usually met with in adult individuals who have been affected with lachrymal tumor or fistula from their infancy, and is not to be confounded with that which depends upon an exostosis, or a deviation of the bones, &c.; it is owing as I think to this, that the canal ceasing to furnish a passage to the tears, no longer grows, and undergoes a suspension in its development, which prevents it, at a later period, from being in relation with the rest of the organization; it is in fact the canal of a child in the orbit of an adult. If the explanation which I give of this fact be correct, we should be prepared to meet with still more difficulties for the insertion of the canula in persons affected with fistula lachrymalis from childhood, than in others. I have operated in five instances under this condition of things. A young man twenty-three years of age, who had been affected with a double lachrymal tumor from the age of eight years, and who died at the Hospital of La Pitié in 1834, enabled me to ascertain, by dissection, the existence of this species of contraction. Monro and M. Lenoir appear to have noticed similar facts. It is moreover quite natural, that not only fistulas from childhood, but also very old fistulas should, in general, be accompanied with a contraction of the osseous canal, if it is true that the tears then cease to flow into the nose. Since the alveoli, like other osseous cavities, shrink (*s'affaissent*) when they have been deprived of the bodies by which they were accustomed to be occupied, we may without difficulty conceive that the nasal canal would have a tendency to contract, should it remain a long time without giving egress to the tears.

In other persons I have found the *nasal canal* greatly *dilated*, and in the form of a funnel at its upper part. This result, which is owing to the protracted distension of the sac properly so called, prevents the canula from remaining in its place but with great difficulty, causes it to mount up towards the forehead, or to fall almost inevitably into the nasal passage, at the expiration of a few weeks.

[*The extirpation of the lachrymal gland for the cure of fistula lachrymalis*, was performed with partial success in 1843. (*Revue Méd. de Paris*, December, 1843,) by M. P. Bernard; the weeping moisture, however, continued. This operation had been suggested for the disease in question by MM. Nannoni and Biangini, and has also been performed in extirpating the globe of the eye for cancer, (see *Arch. Gén.*, Avril, 1844, pp. 501-503.) M. Bernard found the gland hypertrophied. T.]

### ARTICLE III.—EYELIDS.

#### § I.—*Ectropion*.

Two causes may lead to the reversion of the eyelids outwards, the protrusion (*boursoufflement*) of the conjunctiva and the narrowing (*raccourcissement*) of the skin. This last condition, or *ectropion*, properly so called, is the most serious.

A. *Ectropion from exuberance of the conjunctiva*. This first case, which is generally the easiest of cure and the most rare that we meet with, presents itself under the acute stage or in the chronic form.

I. If the malady is recent, *cauterization*, which had already been recommended by G. de Salicet, by means of a particular kind of cautery, will ordinarily suffice. M. J. Cloquet has in this manner effected the cure of an ectropion of the conjunctiva, which had existed more than a year. Saint-Yves and Scarpa particularly eulogize nitrate of silver in such cases. A good many of the dry collyria would produce the same effect. Calomel and sugar, tutty, the white oxyde of bismuth finely pulverized, with an equal part of sugar candy, especially, have enabled me to effect cures that were truly surprising and exceedingly prompt, by applying them in small quantities (*par pincées*) morning and evening, on all the engorged parts. Cauterization with nitrate of silver, I have found to answer in many patients, while the nitrate of mercury became indispensable in two others in 1837, at the hospital of La Charité.

II. *Excision*.—When these resources have been tried in vain, we may, in a case of necessity, imitate Anel, by passing a noose of thread through the skin near the lids, and act upon it by drawing upon it above, in order to readjust the diseased lid to its normal position, and apply at the place where the thread is, as recommended by J. Fabrice and Solingen, adhesive plasters, by which we attach its other extremity upon the forehead for the lower lid, and upon the face, on the contrary, for the upper; but besides that such means would scarcely ever succeed, it is infinitely more simple, sure and prompt to excise the conjunctiva. This also is the method adopted by all the moderns, and the one which Antylus had already recom-

mended, and which Hippocrates himself advised though obscurely, when the scarifications performed by his ophthalmoxia did not succeed. While an assistant keeps the eyelid turned back, the surgeon with a good pair of dissecting forceps in his left hand, embraces a fold of the diseased membrane sufficiently large to restore the eyelashes to their normal direction, but not so much of it as to turn them inwards; excises this fold from the great angle towards the smaller angle of the eye when he operates on the right eye, and in an inverse direction for the left eye; endeavors to include in his incision the conjunctiva only, and to cut rather in proximity to the globe of the eye than to the palpebral border; and, moreover, for the performance of this excision makes use of a straight pair of scissors, or a pair curved flatwise. A very sharp bistoury or even a good lancet would also attain our object, but the scissors are the most convenient. The blood, which at first flows out abundantly, soon stops of its own accord. The operation is now terminated, and for the subsequent treatment we proceed in the same manner as if the patient was affected with an ordinary or traumatic ophthalmia.

In cicatrizing, the wound pushes back the convex border of the tarsal cartilage towards the skin, and thus by shortening the internal surface of the eyelid, replaces it in its natural relations. To perform this excision, Paul of Ægina in lieu of forceps passed a thread transversely from one ocular angle to the other, in order to raise up the conjunctiva. This excision in ectropion, which is disconnected with external cicatrices, is an operation so natural, that we have reason to be surprised not to find it adopted by all the ancient authors. Though it be true that it was performed and described formerly, by a number of authors, it is nevertheless a fact that M. A. Severin is the first, who after having obtained a great many cures by it, established it as a fixed principle in surgery. The remarks of Severin (*Médec. efficace*, part 2, chap. 33,) on excision of the conjunctiva, were forgotten like those of his predecessors, when Bordenave (*Mém. de l'Acad. de Chir.*, t. XIII., p. 150,) proposed it as a new operation, and endeavored to demonstrate all its advantages. It must be evident to whoever reflects a moment on this subject, that the best mode of bringing into their proper line the internal and external coverings of an everted (*renversée*) eyelid, must consist in shortening that which is too long, when we cannot or ought not to elongate that which is too short. Such was the reasoning of Bordenave, and since that time the excision of the conjunctival protrusion (*bourrelet*) in ectropion, has been adopted as a general process in practice. Some surgeons (see Carron du Villards, *Guide Pratique*, etc., t. I., p. 342.) under the impression that they could render this process more efficacious, have suggested that it would be advisable after the excision is terminated, immediately to raise up the border of the eyelid towards the eye, and to keep it adjusted in this manner by means of strips of adhesive plaster or bandages, in order to favor the approximation of the two lips of the wound which has been established upon the conjunctiva. Others, as Dzondi (Guthrie. *Maladies de l'Œil*, 1830; Carron du Villards, t. I., p. 343,) especially, have gone so far as to propose the excision of cutaneous cicatrices,

when any exist, or to make a semilunar incision upon the root (la racine) of the eyelid, in order to enable the plasters or bandages to straighten with more facility the ciliary border. But it is evident that such accessories would only tend to complicate the operation, and that they will not be retained.

III. The only treatment in fact, therefore, that can be advantageous, when there exists no loss of substance, or organic alteration in the tissue of the skin itself, consists in astringents and caustics, or excision of the conjunctiva by the method of Bordenave. The only modification, perhaps, under such circumstances which might be proposed with advantage, would consist in cutting the flap (or fold) of the conjunctiva, in such manner that its anterior border might be made to approximate as near as possible to the free border of the lid, and then to unite the two lips of the wound by a few points of the simple suture. It is probable that we would by this means abridge the time of the cure, by avoiding the inequalities of an internal cicatrix.

B. *Ectropion from shortening* (raccourcissement) *of the skin*.—Bridles and cicatrices, which are sometimes left as the consequence of burns, wounds and ulcers of the face, frequently produce an ectropion much more difficult to destroy than the preceding. Desiccants and caustics applied upon the palpebral conjunctiva are then no longer of any use; and it would be fruitless to attempt to re-adjust the lids by means of threads or plasters. Cauterization with the red-hot iron, and excision of the relaxed surface itself, are usually insufficient. Many practitioners, even among the moderns, admit, that the disease may then be considered as incurable. It is in such cases especially, that blepharoplasty may be called into requisition. [See Vol. I., also our notes on this subject in that volume. T.]

I. *Method of Celsus*.—Up to the time of Boerhaave and Louis, an infinity of processes were practiced in order to elongate the external surface of the eyelid thus reversed. Some with Demosthenes of Marseilles, Celsus (Lib. VII., cap. 7,) and A. Paré, proposed to make upon the skin a semilunar incision, with its horns turned towards the opening of the eye; others confined themselves to a transverse incision, the lips of which they endeavored to keep apart, by filling the wound with lint or any other foreign body; others, like Paul of Egina, and Acrel, endeavored to destroy effectually all the bridles and cicatrices, either by making simple incisions upon them, excising them with the bistoury or scissors, or by strangulating them by means of a ligature. At present it is admitted, that these different operations, far from being advantageous, are almost always hurtful, and that in spite of every precaution, the wounds which result from them, shorten the integuments of the eyelid in place of favoring their elongation.

Though it be true that the ancient method of Celsus is frequently the most inefficient in cases of ectropion from alteration of the skin, it is, moreover, also true, that it may sometimes succeed. M. A. Petit (*Obs. Chir.*, p. 175, obs. 94,) gives a curious instance of it; there existed a breadth of scarcely three lines between the tarsal cartilage and the eyebrow; the conjunctiva was incised without any benefit; when the external semilunar incision, and in such manner as

to comprise only the skin, was then resorted to, and the lips of this incision kept apart by lint. The bottom of the wound by healing up (par dessication,) was transformed into a cicatrix of three lines in breadth, and the eyelid was thus enabled to cover the eye as in health. M. Malvani, (*Journ. Gén. de Méd.*, t. 108, p. 28,—or *Arch. Gén. de Méd.*, t. XXI., p. 273,) and Pellier de Quingsy, (*Obs. sur l'œil*, p. 502, obs. 201,) moreover, who relate facts borrowed from Daviel and Marchand, equally prove that this method does not deserve all the blame, which following the example of Herlse, who wrote in 1668, the moderns have generally reproached it with. It is, however, to be considered that it is exceedingly uncertain, and that it is scarcely worthy of being revived at the present day.

II. *Process of Antylus and M. Adams.*—In 1813, M. Adams, an English oculist, proposed for difficult cases a process which he supposed he had invented, but which M. Martin (*Thèse*, Paris,) attributes to Physick and M. Bouchet, and which is found in part described in Aetius, (*Serm.* 3, cap. 61, 62.) A triangular flap or V, whose base corresponds to the eyelashes, is cut out at the expense of the affected eyelid. The two sides of the division are then reunited by means of suture. The advice of M. Adams has been adopted in France by Béclard, and especially by M. Roux. I have seen it employed, and often employed it myself successfully. Antylus (Peirylyhe) who made his incisions from the adherent to the free border of the lids, was careful in dividing only the conjunctiva, tarsal cartilage and orbicularis muscle; of leaving, in a word, the skin intact, which manifestly distinguishes his process from that of the English surgeon. M. Adams and M. Roux first seize the eyelid with a ligature forceps, then cut on each side through its whole thickness, and in this manner circumscribe the triangle mentioned above, by commencing at its base. The blood which immediately runs out copiously, and which comes from the ciliary or palpebral artery, soon ceases of itself. To reunite, M. Adams restricts himself to a single point of suture placed very near the eyelashes. M. Roux proceeds precisely as in hare-lip, that is to say, that with one or two short, strong pins, or those little pins called minnikin pins, (camions) he constructs the twisted suture. In place of the bistoury, it would be as I think, more convenient to employ a good pair of scissors, as I have frequently done. The operation is then more prompt and certain, and the section of the tissues neater and incomparably more easy. Also, I cannot see that there would be any use in giving more than two or three lines breadth to the base of the flap to be cut out, or to prolong its extent beyond the tarsal cartilage.

III. *Process of M. Walther.*—In a patient in whom the ectropion occupied only the temporal half of the eye, M. Walther, (*Bulletin de Férussac*, t. XIII., p. 77,) after having extracted the eyelashes, seized with a forceps the outer extremity of the lower lid, which he divided through its entire thickness as far as the temple, then did the same for the upper lid, and removed the flap of soft parts thus circumscribed. The two lips of the wound approximated from above downwards, were kept in contact by two points of suture, and the patient recovered perfectly. This process, it is seen, is no other

than that of M. Adams, applied to the smaller angle of the eyelids, and cannot be applicable except in cases similar to that mentioned by M. Walther.

IV. *Process of M. Key*.—In 1826, M. Key had to treat an ectropion, which MM. Travers, Tyrrell and Green had vainly endeavored to cure by the ordinary methods. M. Key, supposing that the cause of the reversion of the lid in this man might have depended upon the spasmodic contraction of the orbicularis muscle, made a transverse incision in the skin, and penetrated little by little as far as to the convex side of the tarsal cartilage; directed an assistant to keep the two lips of the wound apart, and was then enabled to seize with the forceps a bridle of fleshy fibres, which he divided by means of a very sharp pair of scissors. The operation was attended with entire success. I do not know if practitioners will adopt the views of M. Key; I am not aware that they have been precisely stated; what is certain is, that we cannot well conceive of the existence of these supposed spasmodic contractions, nor how the excision of a portion of the orbicularis muscle of the eyelids can remedy ectropion; nevertheless, as in surgery especially, as soon as a fact is averred, whether it is comprehended or not, prudence recommends that it should be admitted, I have not thought it proper to pass by in silence the operation of the English surgeon.

V. *M. Brach*, (Kleinert's *Répert.*, Février, 1837, p. 22,) who proposes to circumscribe and then excise a quadrilateral flap of the integuments, and to have recourse afterwards to the suture, appears to me to have intended to speak of, or to propose an improvement for the treatment of entropion, rather than that of ectropion. The same remark I think may be made of M. Jacob, (*Dublin Hospital Reports*, vol. V., p. 390,) who imagines the operation may be rendered more sure, by confining ourselves to the division of the temporal angle of the eyelids.

VI. The process of M. Dieffenbach, (*Bulletin de Férussac*, tom. XXVI., p. 97,) consists in an incision on the base of the eyelid, with a view of penetrating in this manner to the internal surface of this organ, and to draw its conjunctiva with the convex border of the tarsal cartilage outside, in order to fix them by means of a suture in a fold of the skin. This, however, is an operation which it appears to me ought not to have the preference but in a very small number of cases, and which would expose to a deformity nearly as great as that of the ectropion itself.

VII. Should any of the processes of which I have hitherto spoken, not appear to be suitable, and should the shortening of the skin be considerable, we should have at our command the resources of blepharoplasty, such as I have described it in another part of this work. In such cases I think satisfactory results might be hoped for from the *method of Jones*, even more than from the modification proposed for blepharoplasty in general by M. Hysern of Madrid, (*De la Blepharoplastique temporo-faciale*, Madrid, 1834,) though this modification, which I had not an opportunity of speaking of at the proper time, and in favor of which the author relates two successful examples, is in other respects very ingenious. The method of Jones has the immense advantage of not substituting a deformity in place of

that which we wish to destroy, and of being easy of execution and devoid of serious dangers. I had suggested it in 1834, and I still believed myself the inventor of it in 1837, when I learnt that M. A. Bérard made a trial of it without success, and that M. Jones had employed it in two instances with advantage. M. Sanson, who, according to M. Carron du Villards, (*Maladies des Yeux*, t. I., p. 347,) had also employed it, had no reason to be satisfied with it, since his patient, who was soon seized with an erysipelas, ultimately died. Having finally put it in practice in 1838, I ascertained that it was in reality easy and more prompt than any other, and that we should be wrong in not giving it the preference in cases where all that would be required to adjust the eyelid would be to elongate the skin to the extent of some lines. The young man whom I operated upon in this manner, had had almost the entire left cheek destroyed by a carbunculous affection. The lower eyelid was thus depressed as far down as to a line with the suborbital foramen, and the inferior half of the eye thus remained entirely uncovered. Having cut and dissected the flap, I first united the apex of the wound, to the extent of six lines, by means of three points of suture. Three other points of suture outside, and as many on the inner side, afterwards approximated the sides of the flap and the borders of the solution of continuity that were still free. An erysipelas which made its appearance on the sixth day, did not prevent the agglutination of the parts from being accomplished, and the patient left the hospital at the end of a month with his eyelid raised up to the extent of four lines, though still a little reversed, and in such manner as not to touch the upper lid except under the influence of a very strong contraction of the orbicularis muscle. It would be necessary, moreover, in order to derive all the advantage possible from this operation, to prolong to a very considerable distance the incisions on the side of the base of the orbit, and to dissect the flap nearly as far as the root of the eyelashes, in order to separate its apex as much as possible from its point of departure. It would be moreover necessary to reunite the whole by numerous points of suture, and to endeavor to place in contact the borders of the wound to an extent of from four to ten lines below the point of the V, which moreover would be included by one of the threads or one of the pins. (See Blepharoplasty.) Should ectropion have been caused by any tumor whatever developed in the interior of the orbit, or in the substance of the eyelid itself, it is unnecessary to say that the surgeon should direct his attention to this tumor, and not to the reversed eyelid.

### § II.—*Blepharoptosis.*

When the upper eyelid is kept depressed to such degree as to completely conceal the eye, and without the eyelashes being turned inwards, whether such disease should depend upon the inaction of the levator muscle, or that it is owing to any other cause, if it is ancient, and has not yielded to antiphlogistic or exciting remedies, or to local or general pharmaceutical means, we are necessarily obliged to have recourse to the resources of surgery for this malady. The process ascribed to M. Hunt, (Carron du Villards, *Oper. cit.*, t. I.,

p. 254,) and which I have described above under the name of M. Brach, might in this case be useful. Having excised his elliptical or quadrilateral flap, the surgeon would attach the palpebral border to the superciliary border of the wound, and would thus place the movement of the eyelid under the influence of the occipito-frontalis muscle; we should be wrong, however, to put too much confidence in this remedy. The operation which the fall of the upper eyelid may require, and which is the same nearly as for entropion and trichiasis, has moreover considerably varied.

### § III.—*Trichiasis.*

Hippocrates passèd two nooses of thread through the skin, one near the free border, the other towards the base of the eyelid, and knotted them together in order to turn the eyelashes outwards.

A. *Excision of the integuments.*—But it is to the excision of a transverse cutaneous flap, that attention has been more especially directed. Already carefully described by Celsus and G. de Salicet, this excision is performed in various ways. Acrel, who also proposes it, recommends that we should give a rhomboidal form to the flap. As it appeared to him that it would not always be attended with success, he suggested the idea of incising the integuments above the eyebrow, and to remove therefrom a segment of very considerable size. Celsus and Galen traced out with ink the limits of the flap to be removed, and afterwards reunited the wound by means of a single point of suture. Aëtius advises that one of the incisions, the superior, should be semilunar, and that the inferior should be straight. In place of one point of suture he employed five. Paul of Egina commenced by making upon the internal surface of the eyelid, behind the eyelashes, a transverse incision, extending from one angle of the eye to the other. This was associated with excision and three points of suture. L'Habitant, (*Annuaire d'Evreux.—Jour. de Med.*, 1806, t. XII., p. 368,) cured a patient in five days.

B. *Cauterization of the Skin.*—Rhazes had already endeavored to replace excision by means of caustics. Abul-Kasem made use of the hot iron or quick-lime. Costæus especially, and D. Scachi have eulogized the actual cautery. Ware incised before cauterizing. M. Héling (*Bulletin de Férussac*, t. II., art. 20) and M. Quadri have bestowed warm encomiums upon sulphuric acid. The professor of Naples commences by causing the eyelids to be gently separated apart and then washes, wipes and carefully dries them by means of a fine piece of linen or a sponge. He then, by means of a small bit of polished wood, applies the acid upon the skin which corresponds to the border of the tarsal cartilage, and this to the extent of four to six lines transversely; waits some seconds, in order that the first application of the acid may combine with the tissues; repeats it a second, third and even a fourth time, until the eyelid is slightly crisped outwardly, and he adopts moreover every precaution possible to prevent the caustic from penetrating to the eye.

The *excision and cauterization* of the skin, whether with sulphuric acid, or with potash, as M. Solera (*Bulletin de Férussac*, t. II., p. 417) prescribes, evidently produce the same final result. By both

methods there is a loss of substance. In order that cicatrization may be effected, the lips of the wound are obliged to approximate towards each other. The result is always a shortening of the eyelid and especially of its outer surface. After excision, to which moreover we should give a variable extent, according to the degree of retraction that we desire to produce, should we, after the manner of the first authors who have employed it, as De Beer and M. Langenbeck, have recourse to the simple or quilled (*emplumée*) suture, or should we, as Scarpa recommends, confine ourselves to a simple dressing and union by the second intention? This is a matter of choice, and not of necessity.

C. *Tearing out* (*arrachement*) of the *Eyelashes*.—One of the most ancient methods of treating trichiasis, and especially distichiasis, is the extraction of the deviated hairs, the first idea of which, according to Galen, is to be attributed to Popius. Nothing, in fact, seems more natural, in order to destroy the pain and inflammation which then exist in the front part of the eye, than to remove their cause. Unfortunately it is soon perceived that this remedy is only a palliative, and only relieves but for the moment; and that, in growing out again, the extirpated eyelashes almost constantly retake their morbid direction. Nevertheless it is almost the only operation approved by La Vauguyon, Mâitrejan, De La Motte, and even Richter, when the tarsus itself is not diseased. In order to protect ourselves from such an inconvenience, practitioners proposed to apply a caustic upon the root of the hairs which have been extracted. Sulphuric acid, butter of antimony and nitrate of silver have in turn been lauded for this purpose. If there are only two or three hairs that have deviated, then mere extraction by means of a tweezers (*épilatoire*) very frequently will be found quite sufficient. In repeating it as soon as the eyelashes reappear, we ultimately either destroy their root or change their direction. It is, moreover, an operation too simple, and which too constantly affords relief, not to be made trial of at the very beginning. I have employed it three times with complete and perfect success. Excision with the extraction of the eyelashes, as Forlenze advises, (*Annuaire d'Evreux*, 1810, p. 68,) could have no object.

D. *Cauterization of the Eyelashes*.—Perceiving that all these remedies might fail, some surgeons made trial of the actual cautery, after the advice of Rhazes. In our times, also, some practitioners have found no better method of remedying trichiasis than an improvement on the mode of cauterization employed by so many ancient authors, and especially by Celsus, who made use of a needle heated to a white heat. The form of cauteries formerly employed did not allow of carrying the caloric to a sufficient depth. That of M. Champesme (*Revue Méd.*, 1826) is terminated by a point which supports a large, smooth dilated ball which approximates it a little to the cautery called sparrow-head (*tête de moineau*). Heated to a white heat this point, though very small, maintains the heat sufficiently to form rapidly eschars on every part to which it is applied. M. Champesme asserts that he has seen trichiasis several times radically cured by his instrument; and we could not deny its advantages if, as A. Paré sustains, cauterization of the lashes ought to have the decided preference. M. Carron du Villards, (*Op. cit.*, t. I., p. 307,) plunging

in an insect pin to the depth of a line and a half, in following the direction of the lash in each bulb, afterwards unites together all the pins thus implanted, by means of a silver thread, and then seizes hold of them with a curling tongs (*fer à papillottes*) strongly heated. The process of Celsus, Paré, or of M. Champesme, is by this means rendered as simple as it is easy.

E. *Reversion of the Eyelashes outwards* (eversion).—A mode less severe, and which appears to have been attended with some success, consists in reversing the deviated eyelashes upon the skin of the eyelids. Heraclides, who passes for the inventor of it, kept them there, as did also Acton, by means of plasters. I have succeeded by this mode in a case which had resisted excision of the integuments. Celsus and Galen say that in their time some persons introduced through the skin by means of a needle, a woman's hair doubled in such manner as to enable it to entangle the deviated eyelashes in its noose. According to Rhazes, we succeed full as well by crisping (*frisant*) them with a hot iron.

#### § IV.—*Entropion.*

A. *Excision of the skin*, so strongly recommended by Bordenave, Louis and Scarpa, and almost all the moderns, as a remedy for entropion, is an operation too simple and one that too frequently succeeds not to be made trial of at first. The surgeon being placed in front of the patient, seizes with an ordinary forceps or with his fingers, or with the crutch forceps (*pince en béquille*) of Beer, a fold of the integuments sufficiently large to make the lashes turn upwards and forwards. If this fold should be too large, we should incur the risk of producing an ectropion; if not sufficiently so, we should only obtain an imperfect cure. It is to be excised moreover, in the same manner and with the same precautions as the protrusion of the conjunctiva in lagophthalmia or simple ectropion. After the operation, Scarpa recommends that the skin of the face for the lower eyelid, and that of the eyebrows and forehead on the contrary for the upper eyelid, should be pushed back towards the orbit, and maintained and gathered at this point by means of graduated compresses or adhesive plasters extended from the cheek bone to the forehead. "On the following day," he remarks, "the patient may open his eye, and if proud flesh or fungosities grow up at a subsequent period at the bottom of the wound, they are repressed by nitrate of silver. It is in such cases especially that Beer and M. Langenbeck consider that the suture ought to be employed, in order that the eye may cease as soon as possible from being fatigued by the presence of the lashes. As the skin divided is very thin and very pliant, and as nothing is more easy than to perforate it with a thread, and as there would moreover evidently be an advantage in immediate reunion without gathering the teguments together like Scarpa, on the side of the eye, I cannot see why we should refuse to make use of the simple suture, were it only for the space of twenty-four hours, as is recommended by M. Langenbeck.

B. Avenzoar speaks of practitioners who preferred compressing the flap of the *integuments between two splints*, and thus cause its mortification.

fication, rather than to excise it with a cutting instrument. Bartisch has reproduced this idea under another form, by proposing to compress the skin between two plates of iron united by a hinge. Adrianson, according to Heister, invented another method. By means of an instrument almost similar to that of Bartisch, and garnished with holes, he pinched up a large flap of skin, the base of which he traversed by passing threads through the apertures of the instrument, (pince,) then excised the upper border and left it to itself as well as the threads, which required to be knotted immediately, like so many ligatures.

C. *Excision of the Palpebral border.*—In obstinate cases, Dr. Schreger removes, by means of curved scissors, a triangular flap from the border of the eyelid, including in it the deviated eyelashes, and even goes, according to M. S. Cooper, to the extent of recommending the excision of the entire reversed portion of the tarsus; but we cannot see for what reason this process, already lauded by Heister and De Hayes-Gendron, ought to have the preference over simple excision of the palpebral integuments.

D. *Process of M. Crampton.*—M. Crampton, after having perpendicularly divided the free border of the eyelid to the right and left of the point which supports the deviated hairs, reunites the two vertical wounds which he has made, by a transverse incision of the conjunctiva, then brings the portion of the cartilage thus divided into its natural position, and maintains it there by means of adhesive plaster, or a suspensory to the eyelid. M. Travers, who partially adopts the views of M. Crampton, thinks that in certain cases it would be still better to excise the little flap of the tarsus. The physicians of Bimarestan, mentioned by Rhazes, and who, after having incised the cartilage, traversed it with a thread, in order to turn it outwards; Richter, who in obstinate entropion advises that we should make a transverse incision upon the tarsus, and Paul of Egina himself, who recommends that we should incise the eyelid transversely upon its deep-seated surface, are the sources, as we perceive, from whence M. Crampton obtained the idea of his process, which has again been recently attended with success in a case of ancient entropion, as employed by M. Mackenzie, (*Gaz. Méd.*, 1838, p. 775.) At all events, however, it is a remedy only to be made trial of as an exception in cases where all other means fail.

E. *Process of Guthrie.*—M. Guthrie also incises the tarsus near the ocular angles; but in such manner as to go a little beyond their convex border, afterwards he reverses it with the finger, either towards the forehead or face, according to the eyelid affected. If in falling upon the eye, the cartilage continues to turn inwards, M. Guthrie recommends that we should moreover divide it transversely, and that we should excise a portion of it at the same time with the skin which covers its external surface. Without being important or meriting any great degree of confidence, this process, nevertheless, appears to be less objectionable than the preceding.

F. *Process of Saunders.*—The most sure mode, says Saunders, is to remove almost the entire diseased organ. A thin plate of lead or silver curved like the eyelid, being previously introduced between this curtain and the eye, the operator causes the parts to be stretched;

divides the skin and the orbicularis muscle, behind the eyelashes, a little beyond and in the direction of the tarsus, dissects the flap and terminates by the extirpation of the cartilage. The inconveniences of such a method are too evident to make it necessary for me to expose them. There would be more advantage in following the advice given by M. Jaeger, then by M. Flarer, to excise the cutaneous portion of the free border of the eyelid, respecting its ocular portion, while at the same time removing the deviated eyelashes and their roots.

G. *Process of Vacca*, (*Journ. de Progrès*, t. III., p. 273; *Bull. de Férussac*, t. VII., p. 361.)—The conduct of Vacca appears to me to be much more reasonable. In one of the most obstinate cases of trichiasis, this surgeon proposed to lay the roots of the eyelashes bare, and to destroy them, either by means of a cutting instrument or nitric acid. A concave thin plate, having a transverse groove on its convex surface, is first placed in front of the globe of the eye. An assistant stretches the eyelid and keeps the border confined in the groove of the plate. By means of two vertical incisions of a line long united by a transverse incision, and comprising only the skin, the operator cuts out a little parallelogram, which he reverses towards the side of the palpebral opening, thus lays bare the cartilage, seeks the bulbs of the diseased eyelashes with a forceps, excises them with scissors and burns them, replaces the flap, and makes use of plasters, not the suture, to keep the wound united. The numerous branches, furnished by the palpebral artery to the eyelashes, are cut and bleed freely. Nevertheless, the hemorrhage is never troublesome, and always stops of its own accord.

Delpech, who also eulogizes cauterization of the eyelashes, not of their root, (*tête*), but of their neck, counts chiefly on the establishment of an elastic cicatrix, or an inodular tissue, and consequently prefers union by the second intention. Besides the processes already described under the head of trichiasis, viz. excision of a fold of the skin, eulogized also by Dionis, Saint-Yves, Janin and Gleize, or the the red hot iron, also recently lauded by M. Jobert, entropion has been attacked by the process of Guerin, that of M. Gensoul and that of M. Segond.

H. *Guerin*, (*Journ. de Montp.*, t. II., p. 281; Carrondu Villards, t. I., p. 314,) attributing the disease, without doubt, to a spasmodic contraction of the fibres of the orbicularis muscle of the eyelids, proposed to slit perpendicularly to the extent of several lines, the free, from the adherent border of the eyelid. It is said that Physick, Béclard, and M. Bouchet also had recourse to this method for entropion. We thus produce a coloboma, or a sort of hare-lip of the eyelid, which gives momentary relief, but which cannot effect a definitive cure but at the expense of a very disagreeable deformity. It is consequently a method which should be rejected.

I. The process attributed to M. Gensoul (Carron du Villards, t. I., p. 315, 326, *Gaz. Méd.*, 1832, p. 568,) would be less objectionable. In place of a transverse fold, this surgeon excises a vertical fold of the teguments of the eyelid. In the process of M. Segond, (*Revue Médicale*, 1836,) there is excised successively a vertical and a transverse fold of the skin, so as to unite the ancient method to the process of

the surgeon of Lyons. I do not doubt that we may succeed in this manner in curing entropion in a number of cases; but I scarcely understand the necessity of this species of crucial incision devised by M. Segond and extolled by M. Carron du Villards. An examination of a great number of cases of reversion of the eyelids also has never enabled me to comprehend the utility of the processes of Saunders, Crampton, Flarer, &c., the excision in the manner of Bordenave always having succeeded and appeared to answer with me.

*J. Process of the author.*—To render excision as simple and effectual as possible, whether by the ancient method or the method of M. Gensoul, I adopt the following process: If the palpebral border is reversed inwards, rather towards its extremities than middle portion, I prefer the excision of a vertical fold; in the contrary case I adopt excision of the transverse fold. In the first case I take care that the wound is larger at its lower part than above, and that it represents a sort of oval. In the second case I incise as near as possible to the ciliary border, and I am guarded in giving to the flap a breadth so much the greater at its middle, in proportion as the middle third of the eyelid is found more completely deviated inwards. By means of these precautions, the approximation of the borders of the wound is effected entirely at the expense of the reversion of the eyelashes, and the least loss of substance of the skin produces a decided effect upon the entropion. When, after excision of the integuments, we leave the wound to cicatrize by second intention, the cure may be long and incomplete. To confine ourselves to the employment of adhesive plaster, to approximate the sides of the wound, is very uncertain, and the blood or the tears, which flow in abundance, render the application of the suture quite difficult. These difficulties all disappear by my method, which may be adopted by any body. Having raised up, with the fingers or a good pair of forceps, the vertical or transverse fold to be excised, I immediately traverse its base with a needle, first at the middle and then at each extremity, in order to leave there three threads, each a foot long. I then excise this fold at a line in advance of the threads, and there remains nothing more for me to do than to tie them into a knot, in order to complete the suture and accurately unite the wound. In this manner we avoid all embarrassment caused by the blood; besides that it is infinitely less difficult to traverse the tissues, and that we cause less pain to the patients than if it were necessary to pass successively afterwards the threads through the two lips of the wound. This process, made trial of already in ten to twelve patients, either at the hospital of La Charité or in private practice, has appeared to me to be of such great simplicity, that I have no longer felt it necessary to make use of any other.

*K. Appreciation.*—In simple blepharoptosis excision of the integuments is almost always followed by success. It is also the most effectual remedy for ordinary entropion. If it were a paralysis of the levator muscle, we should have recourse to the process of M. Brach. In trichiasis and entropion, extirpation, extraction and reversion of the eyelashes, in the manner of Heraclides, when their length permits it, or even the process of Hippocrates, might be first made trial of. Then come, 1st. Excision of the integuments, which,

as Physick recommends, ought to be made very near the palpebral border. 2d. Cauterization of the skin by the method of Helling, M. Quadri, M. Solera, or M. Carron, which I have tried in three instances with success. 3d. Process of Vacca for the most severe cases. And, finally, 4th. The excision of the cartilage, according to the views of M. Guthrie, Schreger, M. Travers, Saunders, and M. Crampton, or even by the process of M. Adams, if no other could succeed.

### § V.—*Tumors of the Eyelids.*

If the tumor which occupies either one of the eyelids has not disorganized this curtain but only deformed it, we must destroy it without encroaching on the natural organ.

A. *Encysted tumors* come under this class; being a sort of hydatid productions or sebaceous cysts or degenerate mucipares, they scarcely ever disappear by resolution.

I. *Extirpation*.—When the vinous solution of muriate of ammonia, recommended by Morgagni as well as by Boyer do not succeed, we ought, if the patient is disposed to be relieved propose the operation properly so called. In these cases the ligature, incision, cauterization, and extirpation have been recommended. The ligature has been long since, and very properly, abandoned. Cauterization is equally rejected, unless it should be combined with incision. A needle fixed like a seton in the substance of the tumor, as recommended after a case or two by Demours, (*Arch. Gén. de Méd.*, t. XVI. p. 107,) and by M. Jacquemin, would not in my opinion succeed except by chance. So that it is to extirpation that attention has been more especially directed. In order to perform it, it is altogether useless previously to pass a thread through the tumor whether laid bare or not, as Bartisch proposes, in order to act upon it with more certainty. When it is small and appears to have its seat nearer to the conjunctiva than to the skin, we must seek for it upon the internal surface of the eyelid, because the operation then does not oblige us to go through the tarsal cartilage. The greater projection that it makes externally even ought not always to deter us, for this prominence depends much more upon the pressure of the globe of the eye than upon the precise seat of the tumor. When the skin is changed and very much attenuated, when it is attended with too much difficulty to reverse the eyelid, or when the tumor exists outside the tarsal cartilage, we are then under the necessity of dividing the integuments.

a. *First Process*.—With the thumb placed on the inner side of the tarsus and the forefinger applied upon the skin, the surgeon seizes the diseased lid; reverses it outwardly; presses upon the tumor with his finger in order to make it project in front of his thumb; lays it bare by means of a transverse incision; seizes it with an erigne, which is taken charge of by an assistant; then immediately resumes the bistoury, dissects the tumor, and isolates it in such a manner as to leave nothing of the cyst behind. The little wound which results from this operation requires no particular care, and the cicatrization is effected in the course of a few days. We might also, as soon as the tumor is secured with a hook, and when it has but little volume

and may be readily raised up, excise it with one cut of the scissors curved flatwise. Nevertheless it is important to respect the conjunctiva and subjacent tissues, and to incise rather than excise them, seeing that their destruction would expose to the danger of entropion.

*b. Second Process.*—When from necessity or choice we wish to attack the cyst through the skin, the forefinger takes the place of the thumb, and vice versa. In pushing the tumor the finger stretches the whole eyelid, protects the eye and answers a better purpose than the little cup of lead or silver formerly used, or the plate of gold or leather still recommended by Chopart and Desault. We afterwards divide the integuments cautiously, in order not to open into the morbid body. As for the rest there is nothing particular, and the cure is rarely protracted beyond from three to four days, and without the necessity of dressing.

*c.* In both cases we ought to be on our guard against perforating the eyelid, and as much as possible of wounding the tarsal cartilage, because the cure would in most cases be thereby retarded, and that there might perhaps result from it a sort of fistula or some other deformity. A good pair of forceps may advantageously be substituted for the fingers in most cases. Two forceps, one on each side confided to an assistant, gives still greater facility in stretching the eyelid while the surgeon dissects and removes the tumor. If the operator is sure of his hand, he may moreover himself fix the eyelid upon the globe of the eye by means of his thumb and left forefinger, while with the bistoury in his right hand he makes the division of the skin. Having secured the cyst with an erigne he isolates it, and afterwards separates it without danger. A plate of horn or shell glided between the eye and the eyelid, and which allows of the ciliary border being fixed on the transverse groove which exists on its anterior surface, by means of the nail of the left thumb, gives still greater security and freedom. A man from the country who had in each upper eyelid a fibrous tumor as large as a duck's egg, was cured by M. Fleury, (*Bull. de la Fac. de Méd.*, 1807, No. 2, p. 16,) who, removing an ellipse of the integuments together with the tumor, effected a cure without interfering with the movements of the eyelid.

*II. Modified Cauterization.*—Maitrejan, Heuerman, Nuck, and Loyseau, (*Observat. Chir. &c.*, p. 112, 1617,) before them commenced by largely opening the tumor in order to empty it, and afterwards to cauterize its interior. Chopart and Desault, who profess the same doctrine, use for the second stage of their operation the crayon of nitrate of silver. In adopting this method, Dupuytren gives as the reason that it is more easy, and in every respect as certain as any other, that it ensures us against the danger of perforating the eyelid, and that it is the only one that can be undertaken, when in spite of every precaution, we have penetrated into the cyst while endeavoring to lay it bare. Nothing is more easy than the manual. The organ is seized in the same manner as in the preceding case. With one stroke of the bistoury we divide the skin and small sac, which we empty, or is emptied immediately. With a crayon of nitrate of silver, directed with a certain degree of force upon the bottom of the wound, we cauterize its entire surface. The heterogeneous (coque) mass soon exfoliates, and the wound afterwards heals

up very rapidly. All other things being equal, excision is preferable; but the process of Dupuytren is almost equally as good, and will be found applicable in intractable subjects. Only it is important that the whole cavity of the cyst should be accurately and very strongly touched by the caustic; it is probably from the want of this precaution that a return of the disease took place in the three patients mentioned to me by M. Champion. I have, moreover, employed both modes with like success.

B. The *Chalazion*, the *Grelon* and *Grando*, which are so often confounded with palpebral cysts, are on the contrary small concrete tumors, occasionally fibrous, sometimes as it were caseous or tuberculous, and at other times of a fungous or mucous aspect. Under this last form they often show themselves near the conjunctiva, where I am in the habit of excising them, and afterwards cauterizing their root. It is evident that incision and cauterization would not be applicable to the others, and that extirpation is the only resource which can succeed with them. Like M. Champion, I have observed that many of these tumors have no cysts, and that in order to remove them, we are obliged to dissect them, as for example, we dissect tumors of the breast. I will remark that this small operation is quite painful, and that in certain patients it causes a manifest tendency to syncope.

C. *Erectile Tumors*.—The eyelids are subject also to other tumors. I have elsewhere given examples of the *erectile tumors* which are found here. I will add here that a tumor of this species which occupied the great angle of the eye, disappeared under the action of a compressing bandage and topical astringents, as proposed by M. Carron du Villards, (*Malad. des Yeux*, t. I., p. 353.) Caustic potash appears also to have obtained a remarkable cure of this kind (*Ibid.*, p. 355) with the same practitioner, who also asserts that the hot iron proved very efficacious in the hands of M. Jules Cloquet. It would appear that it is to his father to whom we are indebted for the treatment of erectile tumors by vaccination, and that a tumor of this kind which was situated upon the right eyebrow, was cured in this manner by himself in 1822.

D. *Cancerous Tumors*.—Experience has sufficiently proved that cauterization is an objectionable mode for destroying cancerous tubercles of the eyelids. Though even it should be a tumor of a less alarming nature, it is still with the cutting instrument that we ought to attack it, so often as the degenerescence has extended to the natural tissues. In this part, as in other regions, it is much better to do nothing than to leave a portion of the disease behind and not to trench into the sound parts.

I. When there exists only a *simple tubercle* accurately circumscribed, should it actually occupy only the border of the tarsus, we must isolate it by two incisions united in a V, remove it at the same time with the triangular flap which includes it, and have recourse to the twisted suture to unite the wound by first intention. If the alteration extends more in breadth than in depth; if after its extirpation we are of opinion that we cannot approximate the borders of the wound, we excise the tumor by a semilunar incision more or less elongated, or to a greater or less depth, either with a very sharp bis-

toury, or as M. Richerand prefers, with curved scissors, doing everything in our power not to wound the puncta or the lachrymal ducts. The solution of continuity cicatrizes by second intention. Gradually the integuments approximate to the eye, and ultimately form a border which replaces *in part* the eyelid which has been destroyed.

II. Cancerous degenerations show themselves, moreover, in the eyelids, as upon all other regions of the body under various forms. It does not follow, as has been supposed, because the cancerous tumor has extended as far as the conjunctiva, that its extirpation becomes impossible, or that we are prevented from having recourse to this remedy. M. Champion, who ventured to remove a large cancerous plate, and to perforate through and through the diseased eyelid, nevertheless succeeded perfectly in the case which he has communicated to me.

III. Again, the free border of the eyelid affected with *tylosis* is often transformed into a thick *bourrelet*, which in ulcerating soon assumes the aspect of cancer. But this kind of granulous and ulcerated border, which many practitioners who denominate it *noli me tangere*, prefer attacking by general medications rather than by active topical means, is in general very readily removed under the action of cauterization, by means of nitrate acid of mercury. Having reversed the diseased eyelid outwards and protected the globe of the eye by the usual means, I carefully touch all the ulcerated surface, and even the edges of the degenerated border with a piece of lint, slightly imbued with the caustic. These applications, renewed every four or five days, for three weeks or a month, transform the cancerous into a simple ulcer, and effect such a reduction in the surrounding tissues, that the wound soon cicatrizes and permits the eyelid to recover almost all its pliancy. I have, in this manner, cured a number of persons whom other practitioners had refused to treat otherwise than by extirpation of the eyelid, and it is a method which I cannot too much recommend.

IV. If the case should be one of a cancerous plate, of less thickness than breadth, and which did not extend to the free border of the eyelid, cauterization with the same acid or with the Vienna powder, or better still with the zinc paste, would be preferable to the knife; upon the condition, however, that upon the eyelids themselves, there were no other than the teguments yet altered, and that these different caustics should be applied in such manner as to not compromise the globe of the eye. I have often applied with entire success to cancerous ulcers at the inner extremity of the upper or lower eyelid, or solely and simply at the grand angle of the eye, a plate or thick piece of zinc paste, according as it appeared desirable to cauterize superficially or deeply, and I am of opinion that this caustic ought to be substituted for the bistoury whenever the cancerous ulcer, plate or tumor do not present well defined limits.

#### § VI.—*Ankyloblepharon, Symblepharon.*

A. The *adhesions* which the *eyelids* contract *with the eye* have been observed at every epoch. In order to destroy them, Heraclides, who employed the bistoury, lays down as a precept, that we

should incline the edge of the instrument rather towards the skin than towards the eye, and in order to prevent the reproduction of the adhesion should charge the patient frequently to move the organ of vision in every direction. When they are slight or but little extended, it is sometimes practicable, as Alix says, to tear them out by means of a sound or probe. If they show themselves under the aspect of bridles or lamellæ, and we can succeed in gliding under them, upon the globe of the eye, the blade of a canulated sound, we may, according to the direction of Maitrejan and Boyer, divide them upon this instrument without any danger. It is never allowable at the present day, to raise up the eyelid by means of a thread while we are dissecting it, as was the practice in the time of Bartisch. Moreover, the important point is not the division of these adhesions, but to prevent their reproduction. The movements of the eye, recommended by Heraclides, the plates of lead, gold, or leather, which Solingen and others recommend to keep between the eye and its connections, rarely attain the object in view. The porcelain or glass eye recommended by Demours, and the plate of softened ivory preferred by M. Carron, (*Oper. cit.*, t. I., p. 264,) are scarcely any better; inflammation soon renders the presence of such foreign bodies insupportable. The most prudent course is to restrict ourselves to passing, from time to time, a ring or the head of a large pin between the contiguous surfaces, in order that they may cicatrize separately. It is an operation after all, which, whatever M. A. Severin (*Med. Effic.*, part II., chap. 55, p. 215,) may say of it, ought not to be attempted, except in patients whose transparent cornea has continued unaffected and unchanged, at least opposite to the pupil. The case mentioned by this physician, who was operated upon twice by A. Petit and Dussausoy, (*Obs. Clin.*, art. 13, p. 181,) and afterwards by a charlatan, shows all the danger to be apprehended from an opposite course. Perhaps, however, we should then succeed if, after having slit up the eyelid vertically, as Guérin advises, (*Soc. Méd. de Montpellier*, t. II., p. 285,) we should keep its flaps reversed up to the period of the cicatrization of the bridles, and afterwards reunite them by suture.

B. Congenital or accidental union of the palpebral borders, always a less serious affection, may be complete or incomplete, and may exist alone or at the same time with the preceding infirmity. In the first case, in place of acting with the bistoury from before backwards, as the ancients did, upon the whole extent of the line which the natural division ought to occupy, we first make a small opening near the temple, in order to introduce afterwards, through this incision, a canulated silver sound, which is a little concave on its back, in order that it may accommodate itself to the convexity of the eye. The bistoury, guided by this director, would pass without danger from one palpebral commissure to the other in following the interline of the eyelashes. In the second case the preparatory incision is not necessary. We insert the sound through the remains of the ancient opening, as was successfully done by Hévin, (*Pathol. et Therap.*, t. II., p. 135.) In a patient operated on successfully by Quesnault, (Lelong, *Thèse*, No. 179, Paris, 1819,) there existed at the angle of the eyelids a small opening, which partially allowed of vision through

it. An opening existed also in the cases cited by Botin and Seiler, (Carron, *Oper. cit.*, t. I., p. 257.) Of the three brothers operated on in this manner by G. Lagrèe, (*Anc. Journal de Méd.*, 1760, t. XII., p. 157,) one died on the eighth day from marasmus. After having separated the eyelids, if ankyloblepharon should have coexisted with the disease, we must proceed to its destruction according to the rules indicated above. In the place of the bistoury conducted upon a sound, it would be practicable to employ scissors bearing a ball of wax, as J. Fabricius recommends, or a small button at the extremity of one of its blades, according to the recommendation of Scultetus. But it would be trifling to pass a noose of brass wire furnished with knots behind the abnormal agglutination (soudure), as Duddell did, and to approximate its two halves with the view of gradually dividing the bridge.

Finally, no one at the present day would be so absurd as to imitate F. de Hilden, by knotting the two ends of this noose and attaching weights to it in order to drag it by degrees to the outside. Inasmuch as after every process the disunited borders retain, after the operation, a great tendency to become re-agglutinated, the surgeon should not neglect to place between them, near the commissures, some strands of lint imbued with cerate, nor frequently to separate them apart by means of a metallic stem or ring. To dissect the conjunctiva in order to unite it afterwards with the skin by means of a suture, as M. Ammon recommends, would often fail and presents too many difficulties. Three points of simple suture on each lip of the wound near the commissure, would better attain our object, and would cause infinitely less embarrassment.

C. Simple *phymosis*, or contraction (*rétrécissement*) of the eyelids, should be treated like ankyloblepharon, and requires no other details.

#### § VII.—*Tumors.—Folds at the Great Angle of the Eye.*

Two kinds of tumors, disconnected with the lachrymal passages, have been noticed in the great angle of the eye: one having the caruncula lachrymalis for their seat, the other placed between the integuments and the direct tendon. I know but one fact of this last kind, and which belongs to M. Besson. The tumor, which existed on both sides, had the size and form of an almond: it was extirpated, and the patient got well.

A. The other kind is known under the name of *encanthis*. It has been noticed by a great number of practitioners, and I myself recently met with an example of it in the month of December, 1837, in a young girl of six years of age. The disease may in these cases assume the character of different kinds of tumors, whether fibrous or cancerous; in general, however, it presents itself under the aspect of a small reddish granulated mass, slightly painful, and which seems to prolong itself to a greater or less distance in the orbit, and which also protrudes more or less between the eyelids near the inner commissure. *Encanthis*, unless it should be attacked at the beginning, yields neither to debilitating or resolvent means. The ligature, employed in one instance by Purmann, would be suitable only to pediculated *encanthis*. It will be by means of *caustics* or the bistoury that we shall succeed. Among the first there are scarcely any other

than the nitrate of silver or the nitrate of mercury, which can be applied with safety. Potash, the butter of antimony, and the zinc paste, would in fact expose to too much danger of injuring the lachrymal sac or the nasal extremity of the eyelids. *Extirpation* of the tumor is in itself an operation sufficiently delicate, inasmuch as it would be easy to wound either the puncta, the lachrymal ducts, the muscle of Horner, the tendon of the orbicularis muscle, or in fine the outer wall of the lachrymal sac. The patient ought to be laid on a bed of sufficient height, or seated on a chair; an assistant placed behind steadies the head and attends to keeping the eyelids separate. The surgeon, securing the tumor with an erigne, which he immediately consigns to a second assistant, isolates, by means of a straight bistoury, the morbid mass, first below, then above, then inwardly, in order finally to dissect it from behind forwards, and from within outwards, avoiding with care the globe of the eye. M. Fleury (*Bull. de la Fac. de Méd.*, 1806, p. 157, or 1807, No. 2, 3 année, p. 16.) has extirpated two of them which were of the size of a large egg, but they were situated upon the upper eyelid and not at the angle of the eye. M. Carron du Villards, (*Malad. des Yeux*, etc., t. I., p. 462,) who says that he has twice performed the operation of removing encanthis, perceiving that in one case it was a fungus and in the other a melanotic tumor, considered it necessary to touch the bottom of the wound with the button cautery in his first patient, and with caustic potash in the second. The palpebral artery, which is ordinarily divided by this operation, sometimes gives rise to a kind of hemorrhage which is quite abundant, but which simple tamponing generally arrests without any difficulty. The wound is then filled with small balls of lint, after which a fine piece of linen perforated with holes and imbued with cerate, and then a plumasseau of lint, are placed above to cover the great angle. After this nothing more is required to keep on the dressing than to envelope the whole with a compress and a few turns of bandage in the form of the monocle. After the first dressing we reduce every day the size or the number of the small balls of lint, and the wound generally cicatrizes in the space of from fifteen to twenty days. It was in this manner that M. Marchettis succeeded in detaching a meliceromatous tumor which extended over even a part of the transparent cornea, but he had recourse to the scissors to terminate his operation.

B. *Epicanthis*.—Should the fold of integuments, which from the root of the nose sometimes advances forward in the form of a crescent upon each side, as if for the purpose of covering the caruncula lachrymalis, have too great an extension, patients might readily be relieved by means of an operation which MM. Ammon and Carron, who designate this deformity under the name *epicanthis*, have frequently employed with success. Raising up the skin at the root of the nose, a vertical elliptical flap is excised, of such dimensions that the approximation of the lips of the wound by suture will immediately cause the disappearance of the two angular crescents. If before excising it we should pass pins or threads through the base of the cutaneous fold, the operation would be still more simple.

[Mr. Dalrymple, a surgeon of London, (*Cormack's Journ.*, October, 1843, p. 952,) has had occasion to remove from the upper eyelid an

encysted tumor about the size of a pea, composed of closely agglutinated epithelial scales, containing granular earthy molecules, instead of being composed as is usual of thin transparent laminæ, with a central nucleus. T.]

#### ARTICLE IV.—ORBITAR CAVITY.

*Loupes*, encephaloid masses, aneurisms, exostoses, &c., may be developed in the interior of the orbit. *The lachrymal gland* itself sometimes acquires a considerable volume in passing into the condition of schirrhus. These different lesions, whose especial peculiarity is to push the eye forwards, and at the same time to incline it towards the point opposite to that at which they are situated, have often given occasion for its extirpation. Nevertheless, so long as the globe is not itself implicated in the degeneration it may be saved. This is indisputably demonstrated by an elegant operation of Acrel, the case related by M. Cantoni, (*Journal des Progrès*, t. XIII., p. 256,) that of M. Gerdy, (*Archiv. Gén. de Méd.*, t. VIII., p. 339, 2e série.) and the practice of Dupuytren, (*Clin. des Hopit.*, t. III., p. 196.) An ancient memoir of Daviel and Guérin of Bordeaux proves, on the other hand, that the lachrymal gland has often been extirpated with success by those two surgeons. M. D. Lasserre (*Cas de Chirurg.*, &c., p. 52, fig. 15,) has extirpated from the orbit of a woman a cyst which strongly protruded the eye outward, and the interior of which was cribbled with hairs. Even osseous tumors may be removed without injuring the eye, either by the chisel and mallet, or by tractions or well-directed movements, as is proved by the case related by M. Sultzer. The rules to be followed for extirpation, either of the lachrymal gland or of any other tumor situated in the orbit, will have necessarily to vary according to the volume, form, nature and seat of the disease. If, for example, it was only a cyst filled with matters more or less liquid, nothing more might be required than to plunge a bistoury into it, and to keep its cavity open by means of a meche of lint. MM. Schmidt and Rutdhoffer, in fact, who have often met with cases of this kind, consider that puncture with a trochar would be sufficient. Ware (*Mal. des Yeux*, p. 188, 1805,) cured his patient of a serous cyst, which he had in the orbit, by means of sixty-three punctures. Guérin of Bordeaux, supposing that he was to extirpate the lachrymal gland or a cancer, perceived, after he had passed through the eyelid, that he had fallen upon a tumor filled with semi-liquid matters; he opened and emptied it, and introduced a tent into it, after which the cyst exfoliated on the twenty-first day. Spry, who fell into the same error in 1755, would have probably preserved the sight of his patient if, instead of going on to extirpate the eye, he had had the prudence of Guerin. The liquid humors mentioned by St. Yves, (*Mal. des Yeux*, p. 188, 1805,) Pellier, (*Obs. sur l'Œil*, &c., p. 40,) and M. Graefe, (*Archiv. Gén. de Méd.*, t. VIII., 2 série,) the collection of hydatids described by M. Lawrence, (S. Cooper, *Dict. de Chir.*, &c.,) and M. Travers, (*Synopsis*, &c., p. 229, 235, 1821,) the meliceroma, steatoma, glairy cysts, and purulent collections, indicated by St. Yves (*Oper. cit.*) and MM. Lawrence, Richerand, Guthrie, (*Mal. des Yeux*, p. 147, 148,)

and Travers, (*Oper. cit.*, p. 229,) are to be treated in the same manner.

## § II.

In respect to *solid tumors*, there are two modes of removing them. Whether they are osseous or osteo-fibrous tumors, as in the cases of Baillie, MM. A. Cooper, Crampton, (Mackenzie, p. 56,) and Travers, (*Loc. cit.*) fibrous, adipose, or cartilaginous tumors, like those mentioned by M. Mackenzie, (*Ibid.*;) or even exostoses, properly so called, examples of which are given by Sue, J. L. Petit, (*Mal. des Os*, t. II., p. 303,) and Brossaut, (Mackenzie, *Op. cit.*, p. 48, 1830,) they are notwithstanding to be extirpated.

A. *Process of Acrel*.—The whole thickness of the eyelids is to be divided in the natural direction of their curvature, near their root, and upon the point corresponding to the most prominent part of the tumor. An assistant then separates apart the lips of the wound. The surgeon, by means of a narrow bistoury, guided by the forefinger of one of his hands, isolates the tumor from the orbit, secures it with an erigne, dissects its inner surface, in order to separate it from the eye, either by the finger or the cutting instrument, and makes an effort to remove it from its apex to its base. It was in this manner that Daviel and Guérin proceeded, and none of their patients died. Although in one of their cases the tumor had, on its inner side, a groove adapted to the optic nerve, and that in another there supervened an enormous tumefaction of the eyelids with severe fever, all preserved their faculty of vision. It might at first have been doubted if the lachrymal gland itself had actually been extracted; but Guérin dissected it after the operation, and made even a model of it in plaster; the original of which, preserved by him in alcohol, he exhibited to the Academy of Surgery. It is moreover an operation which, at the present day, is perfectly well understood. MM. Todd, Lawrence and O'Beirne have performed it in England with no less success than Daviel, Guérin and M. Duval in France. The treatise of M. Mackenzie gives two other instances of it, and Warner, as well as M. Travers, had already had recourse to it. I have seen a woman in whom M. J. Cloquet performed this operation, so effectually that there was no longer any flow of tears on this side.

B. *Process of the Author*.—In my view, we could attain our object better than by the process of Acrel, if we were to commence by prolonging the external commissure towards the temple in such manner as to be able to reverse the eyelids. Different trials have satisfied me that by acting in this manner we may readily lay bare the two outer thirds of the orbital circumference. This being done, the surgeon separates the tumor he is about to remove from the osseous cavity which contains it, by dividing the cellular tissue from its external surface; dissects it down to its greatest depth, isolates it with every possible precaution, either from the muscles, optic nerve, or globe of the eye itself, and draws it to the outside by means of the finger or an erigne. For more facility, it would be well perhaps to circumscribe it also by a semilunar incision on the side towards the transparent cornea.

It must undoubtedly have been through inadvertence that an ob-

jection has been made to this process of incurring too great a risk of wounding the ducts of the lachrymal gland, (*Archiv. Gén. de Méd.*, t. VIII., p. 354, 2e série;) for if they required the attention, this process would enable us to respect them still better than that which consists in penetrating into the orbit through the upper eyelid.

C. *Séquelæ*.—After the operation there sometimes succeeds such an extensive swelling that it is not unusual to see the eye at the end of three or four days make as striking a projection as it did before. But this condition of things soon subsides. In the space of from ten to thirty days everything returns to its normal condition, and the cure usually takes place. Immediate reunion ought not be attempted in either process, since the cavity which is left in the orbit, cannot immediately be filled up, and that the tissues, lacerated rather than divided are obliged to suppurate. In a patient whose wound closed up too rapidly, Guérin saw supervene symptoms so formidable that he found himself obliged to break the cicatrix with a sound. All that is necessary then, is to dress with a meche or tent imbued with cerate, to approximate the wound at the palpebral angle, if it has been found necessary to divide it, and to cover the whole with plumasseaux, and then by some compresses, which are kept in place by the bandage called the monocle. When the suppuration is established the dressing should be renewed every day. Injections often become necessary, and we do all in our power to enable the solution of continuity to close up from the bottom to the exterior. If by traversing the eyelids we should render the operation more easy, even though the deformity which it involves would necessarily have to be greater, we ought to give the preference to this manner of proceeding; but unless the tumor should have acquired an enormous volume this is not the case. The incision of the outer palpebral angle will always enable us to procure a sufficient degree of separation, even though there should have been alteration of the bones, to enable us to remove the tumor as well as the necrosed splinters, as was the case in one of the patients of Guérin. In a case of M. Hope, the tumor, which had existed for seven years, had so elongated the optic nerve, that it became necessary to push back the eye with the hand, and to keep it fixed there by means of a bandage; the cure, nevertheless, was complete. In a young woman whose indocility was uncontrollable, M. Wardrop bled her to the amount of fifty ounces of blood, in order to produce syncope, which enabled him to perform the operation with so much ease and success, that the patient coming to herself, could scarcely believe it. In a case of pancreatoid sarcoma mentioned by Bouttate of Moscow, (Abernethy, *Mémoires de Chir. étrang.*, t. II., p. 453,) the tumor, which was seven inches in length, and three and a half in circumference, weighed two pounds and a half. It was intimately united with the conjunctiva, which it pressed upon; but it was not difficult to isolate its base from the cornea, which had preserved its transparency. After the ablation, the patient recovered his sight.

## ARTICLE V.—GLOBE OF THE EYE.

§ I.—*Foreign Bodies.*

Numerous and various kinds of foreign bodies may become fixed on the eyelids or on the front part of the eye, in the same way as between the eyelids and the eye. Besides the ordinary signs which reveal their existence, I have ascertained, like Andrieu, (*Avis. au Citoyens*, &c., p. 19, 1780,) that pungent and fixed pain corresponding to the middle of the upper eyelid, indicates the presence of a foreign body upon the cornea; in the same manner as those which are concealed in the oculo-palpebral fold of the conjunctiva, are announced by a dull pain, which corresponds to the upper border of the tarsal cartilage.

A. The *ciliary border* of the eyelids is sometimes invaded by insects. A young peasant girl who had this part of the coverings of the eye transformed into a brownish colored border, and who suffered from it to a considerable degree, carried there so great a number of pediculi pubis that M. Champion, who was then consulted, could have never believed it possible that so many of them could have attached themselves upon so narrow a space. In such cases, all that is necessary is, to cause the parts to be rubbed with mercurial ointment, that of white precipitate, or the pomade of Desault, and no operation is to be attempted. There have been seen, moreover, different sorts of worms either in the ulcerated border of an eyelid, or at the bottom of the oculo-palpebral groove. We have already an example of this kind in the *Ephemerides* of the *Curiosa Naturæ*, and we owe to M. J. Cloquet the history of a man, who had the eye and the orbit deeply excavated by a species of worm known under the name of *asticot*. I have also met with a patient, who being habitually uncleanly, and for a long time tormented by a ciliary blepharitis, had six enormous asticots at the great angle of the eye, between the inner extremity of the upper eyelid and the caruncula lachrymalis. The mode of destroying them, moreover, is the same as for the pediculus pubis, and other insects. It is also probable that camphor, so much praised by M. Raspail, (*Gaz. des Hôpits*, Novembre et Decembre, 1838,) if it were associated with mercurial topics, would give them still greater efficacy.

B. Foreign bodies of a certain size may also sometimes remain implanted for a considerable length of time in the eyelids or front part of the eye without being perceived there. A young man entered the hospital of La Charité, in 1837, with a sub-acute ophthalmia. The cornea preserved its transparency; a grayish colored chemosis with an erysipelatous tumefaction of the upper eyelid, which phenomenon was more marked in the direction of the temple than towards the nose, immediately struck my attention. The young man, who suffered but little, did not know to what to attribute his malady, which had existed for the space of fifteen days. By dint of researches, I finally discovered in the superior oculo-palpebral groove, the yellow extremity of a body which I immediately seized with a forceps, and which was nearly an inch in length and a line and

a half in diameter. It was a piece of hay-stalk, which had penetrated into the orbit while the patient was asleep upon a cart loaded with hay. Borichius (*Collect. Acad.*, partie étrangère, t. VII., p. 321) speaks of a thorn which in this manner remained for a period of thirty years in the inner angle of the eye before it occasioned any pain, and which ultimately produced a violent inflammation. A stem which was more than an inch long, and which entered the orbit through the eyelid, remained there also, says Willius, (*Collect. Acad.*, t. VI., p. 248,) a very long time without being recognized, though it produced very serious accidents, with delirium and convulsions.

C. *Fragments of whalebone* of a line or two in length have, in the same manner, become lost under the conjunctiva in a patient mentioned by St. Yves, (*Mal. des Yeux*, p. 210, art. 12.) Bidloo, Scharschmidt and Percy (*Chirurg. d'Armée*, p. 112, 113,) give similar instances of pieces of wood, glass and pipe-stem. M. Maunoir (*Corps étrang.*, 1812, p. 212) speaks even of portions of chesnut shells which have thus become fixed on the front part of the globe of the eye; and M. Champion has noticed the same thing. There have also been seen hairs that had grown from the caruncula lachrymalis, as in the case cited by Albinus, and become incurvated outwardly so as to give momentary irritation to the eye. Demours (Séance de l'Académie de Méd., 22d May, 1828) speaks of a barb of a barley ear which had introduced itself into the lachrymal punctum in such manner as to project outside, but to a very small extent. A case also has been mentioned which was noticed by Dupuytren (*Archiv. Gén. de Méd.*, t. XVII., p. 126), and in which an eyelash had, by curving backwards, become entangled in one of the lachrymal puncta. I will add that a woman who thought she had a small tumor on the sclerotic, at the outer angle of the eye, and who had carried this pretended tumor for the space of nineteen months, had there nothing more than a particle of millet seed, which had come out of a bird-cage, and which appeared to have been kept in its place merely by atmospheric pressure. I have seen the same thing on various other points of the globe of the eye, and even on the cornea. In all cases, the little cup reposed by its concavity on the eye, and seemed to have embedded itself into the conjunctiva. I have also found on the cornea small scales, either of cinder or copper or iron, which had retained their position in the same manner for the space of several weeks without occasioning serious accidents. A patient whom I exhibited at the clinique of La Charité, in 1837, had one of these scales in the front part of the cornea for the space of fifteen months, and had paid so little attention to it that it was for another disease that he was induced to come to the hospital.

D. A gold or silver ring, the head of a long pin, a small roll of paper, an earpicker, or any other smooth and round substance, will answer for removing the different solid foreign bodies which continue movable between the eyelids; but it is not always the same with particles of metal, stone, wood, &c., which having been projected upon the organ of vision, become fixed and retained there. In such cases, when we are not afraid of breaking them, the point of a pen, cut in the manner of a toothpick, or any other similar instrument glided upon the front part of the cornea often succeeds in detaching

them. At other times we cannot do this except with the point of a lancet, and in some cases even only by making use of a small pair of forceps skillfully managed. It is only under very rare circumstances, and when the ferruginous corpuscle is scarcely adherent, that the load-stone, as recommended by F. de Hilden, (Bonet, *Corps de Méd.*, p. 393,) (who boasts much of the successes thus obtained by his wife,) could be usefully employed. The same remark would apply to the roll of Spanish wax employed by Deshayes Gendron, or to a piece of amber to attract to the outside particles of straw. When we decide upon the operation an assistant is charged with holding the eyelids apart. The operator directs the point of a lancet or of a very sharp-pointed bistoury to the circumference of the foreign body, which he isolates down to a certain depth in the substance of the cornea, then seizes hold of it with a very fine and well adjusted forceps, draws it while moving it gently for fear of breaking it, and afterwards pursues the same treatment as in a patient having an ordinary ulceration or simple ophthalmia. This operation moreover does not in itself present any difficulty; it merely exacts address and great precision in the movements. Moreover, when the body to be extracted projects beyond the level of the eye, if it is solid and does not penetrate into the chambers, we almost always succeed in detaching it by scraping it with the border or the side of the point of a lancet or cataract needle.

E. If, as I have seen in different patients, grains of powder, or lead, or fragments of percussion-caps, glass, metal, or of a watch-spring for example, should happen to penetrate into the eye, we should, supposing that they could be perceived, not hesitate to cut into either the cornea or sclerotica in order to search for and extract them with an ocular forceps, or cause their expulsion in any manner whatever.

## § II.—*Various kinds of Vegetations.*

A. *Pterygion*.—When, by means of resolvents judiciously employed, we have not been able to disperse the pterygion, and that it advances upon the cornea to such extent as to make us apprehend the loss of the sight, it must be removed by means of the bistoury or the scissors. The section of the vessels which go to it, and which Beer still recommends, its strangulation by means of a thread passed between the conjunctiva and sclerotica, as preferred by La Vauguyon, and also cauterization, have succeeded in more than one instance; but as all these means are uncertain and more difficult of execution than excision, they have generally been abandoned. In order to remove the pterygion we seize hold of it with a good pair of forceps in one hand, at one or two lines from its point; we draw upon it a little towards ourselves as if to detach it; and soon perceive a slight crackling sound similar to that of unrolling parchment. Then it becomes easy to isolate it either from its apex to its base, or vice versa, as M. Flarer recommends, (*Thèse de Lefebvre*, Paris, 1829,) by means of the bistoury or a good pair of scissors. As the cornea rarely resumes its primitive transparency opposite the wound, Boyer recommends with reason, as I think, when the point of the pterygion has approximated very near the pupil, not to prolong the dissection as far as that, but to excise only the posterior four-fifths

of it. Emollient lotions during some days, and afterwards resolvent applications, as in all chronic phlegmasias of the conjunctiva, constitute its consecutive treatment. I have operated for pterygion by this process, in patients who had two, three, four, and even five of them on the same eye; I have never found any serious difficulty in it, and I cannot comprehend either the dangers which M. F. Cunier (*Bulletin Méd. Belge*, t. I., p. 296) charges it with, or the importance of the methods which have been proposed to be substituted for it. When the pterygion is not very thick, Scarpa is of opinion that in the greater number of cases it is sufficient to excise a semilunar flap from it opposite the point of union of the sclerotica with the cornea, and that in other cases we may destroy it entirely; that in order to prevent a cicatrix raised up in the form of a border, we should first detach the apex, then the base, and finally terminate with its middle portion. I do not, however, conceive that this last precaution can be of any great moment, and partial excision, which I have tried in three instances, has not succeeded with me. In all cases it is prudent to follow the advice of Boyer, and to apprise the patient that, notwithstanding the operation, he may not be perfectly cured, because of the species of spot which is too frequently the result of it.

**B. Pannus.**—The periphery of the cornea is sometimes covered by a grey or reddish flattened vegetation, granulated like the back of the tongue, indolent, from a quarter to a half a line in thickness, and advancing more or less, in the manner of a ring, on the transparent portion of the eye. In certain cases, however, this variety of pannus forms only the segment of a circle, while in others there appear to be detached from it semilunar or triangular plates, which prolong themselves a little farther than the rest upon the cornea. M. Graefe (*Revue Méd.*, Mars, 1818, p. 464) gives an instance of one which entirely covered both eyes. Nothing but complete excision or cauterization can remove this disease. If the pannus has but little thickness and is entirely circular, the nitrate of silver answers, and should have the preference. When it is more solid and forms somewhat large plates, excision by means of a lancet or cataract needle held flatwise, (*portée en dédolant*,) followed immediately after by cauterization, is more appropriate. A vegetation of the same kind may be developed upon the cornea and remain completely independent of the conjunctiva. I saw a remarkable example of this kind in a forgerman, forty-five years of age. The plate, which was half a line thick, more than three lines long, and a line and a half in breadth, placed transversely and slightly concave above, was situated below the pupil, and left a very perceptible and perfectly sound strip of cornea between its lower border and the sclerotica. I destroyed it three times with the nitrate of silver, and three times the patient, who was very anxious to resume his occupations, left the hospital before being absolutely cured, and at the moment when there was the best reason to hope for a perfect cure.

**C. Horny Plates.**—M. Mirault speaks of a production which is much more singular still. The cornea of a man affected with trichiasis from his infancy, was covered with a kind of dirty white dry, and as it were, scaly skin. It was probably a xerophthalmia. Similar productions, or such as

were *horny*, have also been encountered on the front part of the eye in certain individuals affected with ichthyosis.

D. The cornea is also liable to other excrescences. Guerin makes mention of a young person of Macon, who had a *fleshy tubercle* as large as a pea on the front part of the pupil, and which he cured by one cut of the scissors. Some of them may be compared to *nævus*. M. Wardrop gives examples of them. In one case, the tumor was granulated, of a brownish color, and but little vascular. It was softer, of a reddish color, and placed half on the cornea and half on the sclerotica, in another patient. In a third case, three *long hairs* proceeded from it, and protruded like a pencil from between the eyelids. The same author quotes a case similar to this last, in the Baron of Gloucester, and remarks that Gazelli had also seen hairs growing from the cornea.

E. Among these tumors, there are some of them that are analogous to vegetations from the mucous membranes. These are a sort of fungus. M. Wardrop has seen two examples; one irregular, granulated, and partially on the sclerotica; the other darker and more solid. In a case cited by Voigtel, a cartilaginous point was found in the centre. Sometimes also the tumor derives its origin from an ancient ulcer. Maitrejan gives an example of this; but it appears that in his patient, the fungus came rather from the interior of the eye, than from the cornea properly so called. These different projections can only be cured by excising them completely; also, we must take care to cauterize the bottom of the wound immediately, if we expect to prevent all return; it is in this manner that Pellier succeeded in a patient who had a tumor of this kind caused by a burn from gunpowder.

### § III.—Cataract.

Although Galen and the Arabs had already pointed out the nature of cataract, centuries passed away before it was generally understood. The pellicle which constitutes the disease is situated, according to Culsus, between the uvea and the crystalline; on the contrary, according to Guy de Chauliac and G. de Salicet, between the iris and the transparent cornea. What contributed most to give prevalence to such errors, was the idea that the crystalline was the seat of vision. Therefore, as soon as Kepler had demonstrated in 1604, that the lens of the eye was no other than a refracting body, an actual surgical revolution was promptly brought about on this subject. Gassendi, who wrote in 1660, as well as Palfin and Marriotte, attribute to R. Lasnier or F. Quaré, the honor of having first sustained the idea that cataract does not depend upon an accidental pellicle, but on an opacity of the crystalline. Schelhamer, who imparted it to Rolfink, had taken the idea from a surgeon of the Hotel Dieu. Brisseau, Méry, P. du Petit, Borel, Tozzi, Geoffroy, Albinus, Bonnet, and Freytag, had also without doubt derived it from the same source. But it is to Maitrejan to whom we are indebted for having placed the fact beyond all dispute. In going from one error they were upon the point of falling into another; in place of never seeing cataract in the crystalline, it was now maintained that it was always there.

Ph. de la Hire, Freytag, and Morgagni, did not succeed without difficulty in establishing the fact, that this malady may also be produced by the opacity of the capsular membrane. It was S. Muralt, Didier, Heister, and Chapuzeau, for whom it was reserved to demonstrate, without rejoinder, that cataract is produced by opacity of the crystalline, that of its capsule, or of the matter in which it floats, and not always that of one part only.

A. *Cure without an operation.*—Though since the time of Celsus, who was the first that has spoken lucidly on this subject, it has been acknowledged that confirmed cataract is rarely cured except by the operation, properly so called, we should nevertheless be wrong in denying absolutely, the efficacy of any other treatment.

The cataract which is seen in scrofulous, scorbutic and syphilitic subjects, or in consequence of an inflammation or any other disease in the neighborhood of the eye, has disappeared in more than one instance, either spontaneously with the constitutional disease, or under the influence of general or local treatment judiciously directed. Maitrejan, Callisen, Alberti, Gendron, Murray, Richter, Ware, and many others, have given examples of this kind. Hyoscyamus applied to the eye according to M. Nostier, or a simple seton to the nape in the opinion of M. Champesme, (*Arch. Gén. de Méd.*, t. I., p. 290,) have succeeded in curing cataracts of very long standing. M. Diétrich recommends that we should arrest its development by repeated punctures to the eye, and M. Schwartz (*Revue Méd.*, 1828, t. III., p. 126) has cured three cases by means of revulsives, &c. With MM. Rennes, (*Archiv. Gén. de Méd.*, t. XXII., p. 206), P. Delmas and Manoury (*Biblioth. Méd.*, 1827, t. IV., p. 185), I have seen it disappear spontaneously. M. Janson (*Hôtel Dieu de Lyons, Compte Rendu*, 1824, p. 83) also gives two examples of this kind. MM. Larrey and Gondret affirm, moreover, that they have obtained similar results by means of moxas, the actual cautery, or the ammoniacal pomade applied upon different points of the head, especially to the sinciput. Without admitting as certain with M. de Blainville (*Nouv. Bull. de Sc. Méd.*, Février, 1835, p. 31,) that the crystalline may be formed by its capsule; without conceding also with M. Campaignac, that cataract is only a symptom of disease of the envelope of the crystalline, it must at least be admitted that the cataract which results quite frequently from wounds of the eye, is to be ascribed as M. Watson (*Arch. Gén. de Méd.*, t. XII., p. 610) asserts to inflammation of the neighboring lamellæ. The repeated experiments of M. Neuner (*Journ. de Prog.*, t. VIII., p. 117; *Bull. de Férussac*, t. XIV., p. 194) have since shown with what facility opacity of the crystalline may be produced, by means of certain liquids introduced into the eye. The experiments and observations still more varied of M. Dietrich, (*Bull. de Fér.*, t. VI., p. 84; *Arch. Gén. de Méd.*, t. XII., p. 295,) Tartra, Beer, and Szen, though contradicted by those of M. Watson, exhibit the decided influence of wounds and certain acids in the formation of some cataracts. A cataract from infancy was cured by the evacuation of a brown matter, by means of a small puncture into the capsule. The crystalline, which was sound, remained, it is said, (*Gaz. Salut.*, No. 5, 1783, p. IV) in its place in both eyes, and the sight was reëstablished!! From hence, without

doubt, came the new method of M. Jungken, (*Arch. Gén. de Méd.*, 2e série, t. X., p. 93.) It is doubtless difficult to believe that the crystalline, which is an inert body and the actual product of an exudation, and which receives neither vessels nor nerves, can recover its transparency after having actually lost it; but pus and other products which may be deposited in front of it, as in the three examples related by M. Boudant, (*Arch. Gén. de Méd.*, t. XXIII., p. 429,) being in more direct relation with the iris or ciliary circle, would be more or less influenced by the particular state of the eye and the general constitution of the individual. It is also well established at the present time, that traumatic cataract very frequently gets well without an operation. The case of cataract caused by a blow on the eye from the branch of a tree, as mentioned by M. Mondière, (*Arch. Gén.*, third series, t. II., p. 352,) ultimately disappeared spontaneously. I saw a similar case at the Hospital of La Charité in 1836.

A young peasant, of fifteen years of age, was struck upon the eye by the free extremity of a small green twig of a tree. A cataract was thereby immediately produced, which was perfect when first brought under my notice, at the expiration of fifteen days. In order to reduce the inflammation which existed in the eye, and also to facilitate the cure of the cataract, I had recourse to bleeding at the arm, a few leeches to the temple, frictions around the orbit with the mercurial pomade combined with belladonna, and afterwards to a large temporary blister over the cutaneous surface of the eyelids. After having become broken up into many fragments, which successively passed into the anterior chamber, the crystalline ultimately became completely dissolved, so much so, that the boy, after having been in the hospital two months, left there almost perfectly cured, and with a pupil which presented only one single small opaque point. I saw a similar result in 1837, in a young lady who wounded her eye with a pair of scissors. Another example occurred at La Charité in 1838. Some of the observations also related by M. Convers, (*Gaz. Méd.*, 1838, p. 513,) fully corroborate this fact. In a child of five years of age, mentioned by M. Gerson, (*Arch. Gén. de Méd.*, 2d series, t. VIII., p. 224,) the cornea having been wounded by the point of a knife, a cataract was thereby produced, which got well spontaneously. Nevertheless, if on changing its color, the crystalline evidently undergoes a molecular action subject to the laws of chemistry, and if spontaneous cataract is not the product of either an electric action, or of that species of oxydation suggested by MM. Richerand and Leroy, it would be still more difficult to refer it constantly, with M. Campaignac, to alterations in the secretion of its capsule. Such being supposed to be the case, we cannot see why, by a contrary combination, it might not sometimes be possible for it to return to its primitive condition. M. Luzzato (*Encyclogr. des Sc. Méd.*, 1836, p. 405,) speaks of a patient who, after having been a long time afflicted with cataract, was cured of it by a violent ophthalmia. On the other hand, the crystalline capsule may be torn and place the lens which it contains in contact with the humors of the eye, which in their turn effect its solution or favor its absorption, facts of which description we have on record. The crystalline having passed into the anterior chamber, in a patient of Ansiaux, (*Clin. Chir.*, 2d edit., p. 161,) ultimately

became dissolved there. This body disappeared in the same manner in the case cited by M. Bobillier, (*Rec. de Mem. de Méd. Chir. et Pharm. Milit.*, t. XVI., p. 240, 1825,) and I have seen the same thing occur in three instances.

B. *Surgical Treatment*.—Surgeons, moreover, have attempted, from the remotest antiquity, to destroy cataract by means of particular instruments. Celsus in fact leaves it to be inferred, that among the physicians of Alexandria there were many, especially a certain Phyloxenes, who had acquired in this respect a very great degree of skill.

*Conditions*.—I. If the *cataract* be *simple*, if it has its seat in the crystalline or has not contracted any unnatural adhesion with the surrounding parts, if the iris retains its power of contracting and dilating alternately, if the patient still distinguishes light from darkness; if no inflammation exists either in the eye or in the periphery of the orbit; if there be present neither cephalalgia, nor a catarrhal affection, nor any general disturbance; if the eyes are neither too projecting or too much sunken in their socket; if the patient is not too much advanced in age, and if he is sufficiently tractable to submit to all the necessary treatment, the chances of success are as numerous as could be desired. When, on the contrary, the patient is enfeebled by age, that spots exist upon the cornea, that the pupil remains immovable, that a greenish tint is observed at the bottom of the eye, that deep-seated pains are felt or continue to exist in the orbit, that a chronic ophthalmia or any other malady tedious and difficult to cure, and more or less serious in its character, exists in the neighborhood of the eye, we cannot count on success. In other words, so often as the crystalline and its capsule alone are diseased, that apart from the cataract the organ is in a natural state, and that there is nothing in the orbit that prevents the reëstablishment of vision, then, whether the cataract be true or false, formed by plastic exudation, (Simmeon, *Bull. de Fér.*, t. X.) or by a return of the crystalline to its embryo condition, (Grandclaude, *Journ. Comp. des Sc. Méd.*, t. XXXI.) whether the cataract be lenticular, capsular, or capsulo-lenticular, anterior membranous or posterior membranous, hard or soft, milky or gypseous, barred, oscillating, stellated, pearly, with three branches or central, purulent, putrid, spotted or trellis-like, marbled, dry or husky, sanguineous, dendritical, yellow, grey or black, the operation should be recommended. In other cases, and especially if it is complicated with infiltration of pus (Dujardin, *Thèse, Paris*, 1830) or blood into the little receptacles of the vitreous humor, it should not be undertaken but as a dernier resource, when every thing had failed, and not until after having forewarned the patient of the slight chances that exist of a cure. Nevertheless we must not allow ourselves to be deterred by appearances.

The *immobility of the pupil* is not a certain sign of amaurosis. Wenzel, Richter, MM. Larrey, Watson, S. Cooper, &c., have shown, as I have often myself seen, that adhesions of the iris or contractions of its opening after an iritis may also produce it, and also that it will dilate and contract itself though the retina be paralyzed. I have many times seen dilatation with immobility of the pupil, in patients affected with cataract without complication of amaurosis.

Others have remained with a movable, narrow and very regularly formed pupil, without recovering their vision. Some patients who could not in any manner distinguish day from night have, after having been operated on, been more fortunate.

II. *Black cataract*, (cataracte noire,) which had already been noticed by Guy de Chauliac, Morgagni, Rolfinck and Freytag, and of which Mâitrejan, Janin, Pellier, Arrachard, Wenzel, A. Petit, Edwards, Coze, (Dujardin, *Thèse, Paris*, 1830,) and MM. J. Cloquet, Riobé, Luzardi and Sanson, (*Journ. Univ. des Sciences Méd.*, Juillet, 1819,) have related examples, is too rare to arrest the attention of an intelligent operator, even in supposing, which is not demonstrated, that it may exist without changing of the color of the pupil. A young girl twenty-six years of age, blind in the usual way that patients affected with cataracts are, had nevertheless the pupils *almost* perfect. The crystalline was first extracted from one of the eyes and then from the other, and the operation, which was performed by M. Roux, (*Dict. de Méd. et de Chir. Prat.*, t. II., p. 108,) was perfectly successful. M. Carron du Villards, (Pasquet, *Lancette Franc.*, t. XII., p. 524,) and M. Robert (Carron du Villards, t. II., p. 271,) have observed similar examples: I also have noticed two cases. Moreover, when no organic lesion nor any serious symptoms render the operation formidable, I do not see why, when the patient is completely blind, we should refuse to undertake it. In such cases the patient can lose nothing, while on the other hand, should there be only one chance in a thousand, it would be uncharitable not to let him have the benefit of it. We must nevertheless absolutely desist from it as soon as there is a certainty of a deep-seated alteration in the eye.

III. *Tremulus Iridis*.—Should the crystalline or the humors be movable, or offer the slightest appearance of tremulus iridis, we should at least be careful not to operate by extraction. The case of a crystalline thickened, and spontaneously depressed, as mentioned by Turquet de Mayerne, was it not in fact complicated with tremulus iridis? (*Prat. de Méd.*, p. 90.) In a man who was in this condition, and to whose solicitation I finally yielded, the crystalline gently issued out of itself enveloped with its capsule a few moments after opening into the cornea, and the vitreous humor was in so limpid a condition that it would have escaped like water, if I had not immediately made pressure on the fore part of the eyes by means of lint. Cerebral accidents supervened and were sufficiently serious during some days, to give me the greatest degree of uneasiness. The left eye suppurated, and the right, although perfectly clear, remained altogether insensible to light. This is a state of things which I have often since met with, and which is imputable to a liquefaction of the vitreous humor. Depression alone may be attempted in such cases, if it is thought prudent to attack the cataract; the operation then produces scarcely any reaction in the eye. It has at least the advantage of causing the disappearance of a deformity by again giving to the pupil all its regularity, and this result is not to be disdained when there is only one of the eyes in a state of cataract. The mobility of the crystalline is sometimes hereditary. Portal (*Malad. Heredit.*, p. 87, 3rd edit.) gives an instance of two brothers who were thus affected, and whose father had the same peculiarity.

The crystalline rested in part in the anterior chamber, as in the two patients noted by me.

IV. *Anomaliës.*—*False cataracts*, which are almost always complicated with affections of the iris, or some other membrane of the eye, are not generally so easy to destroy as the true cataracts. All other things being equal, the crystalline cataract is of a less serious character than the capsular, or that of the humor of Morgagni. I have seen patients *completely blind*, though their *crystalline* was only *slightly opaque*. In others, the *cataract* appeared so *advanced* that nothing more was required for its maturity, and nevertheless *they could still see* very well. A dealer in grain in the environs of Paris furnished me a very fine example of this species in 1838, at La Charité. Arrived at the Hospital from his own residence without a guide, he could count his fingers and distinguish faces, though to appearance his two cataracts were as complete as possible. I have had occasion to remark, that persons who could see in spite of their cataract, had an opacity of the crystalline only, or of the posterior capsule, and that in them there existed a certain free space between the iris and the lenticular apparatus.

V. *A light* which is made to pass in front of the eye of a patient who does not see, will, provided there be no opacity in front of the vitreous humor, produce *three images*, one anterior, regular, (*nette*,) and straight, one deep-seated, large, diffused, and also straight, and a third in the middle small, pale, and reversed. The anterior image alone will remain in the case of complete cataract. But it is the deep-seated image only which is effaced when the opacity is concentrated upon the posterior layers of the crystalline or its membrane. This method, which I have often tried, and the use of which has been sanctioned by M. Janson, (Pasquet, *Thèse, Paris, 1837*,) has however appeared to me to afford very little reliance. It is useless in ordinary cases, and I do not think it would be sufficient in doubtful cases.

VI. *Ages.*—In children, the operation, though difficult to be performed, succeeds better than in adult age, and so much the better after that, as the patient approaches nearer to the middle period of life. The table arranged by M. Drache (*Thèse, No. 180, Paris, 1837*,) shows what are the influences of age and other personal conditions on the formation of cataract. Almost all authors agree with Sabatier, that we ought not to recur to the operation except in persons who are old enough to know the benefit of it; that it ought not for example to be employed before the tenth or fifteenth year.

a. The intractability of *children*, the little anxiety they have about obtaining their sight, and the dangers we should have to incur in endeavoring to operate upon them in spite of their wishes, and the difficulty of subjecting them to the necessary precautions, are the principal motives upon which this precept is established. But if in the tender age the operation is more delicate and more hazardous, and the membranes of the eye from being more tender, thinner, and less dense, are more easily penetrated; the eye is less movable, the pupil more large, and such patients, dreading only the pain, are in nowise concerned about the consequences of the operation. As this operation is rarely accompanied with severe pain, I cannot see how in such

cases it can have any thing in it of a very formidable character. It is, moreover, always practicable to confine even the youngest subjects, and to keep their eyelids separated apart. The eye is an organ essential to the development of intelligence, and the source of the greatest number of our ideas. If its functions should be found abolished at birth, its development ordinarily remains incomplete ; it acquires gradually an excessive degree of mobility, which renders the operation much more delicate, and diminishes the chances of success.

In conclusion, when we reflect upon the importance of the education of children, it would be really difficult not to admit with Ware, Lucas, Saunders, Travers, Beer, &c., the advantage of relieving them as speedily as possible of cataract. Nevertheless, I am not of opinion that we ought, in such cases, to select the age of two years, as Farre recommends, or the period of six weeks, with M. Lawrence, rather than the first or third year.

b. In *old men*, the disease being almost a natural consequence of old age, the operation is inadmissible, except they earnestly desire it, and are moreover found in the best conditions possible. I have performed it, however, in a man of eighty years of age, and in a woman of eighty-five, with a successful result, which is far from being always obtained in young subjects.

VII. The five hundred cases of cataract which I have noted up to the present time have not enabled me to assert that males are more frequently affected with it than females. We see by the researches made by M. Maunoir, (*Thèse*, No. 345, Paris, 1833, p. 13,) that out of one hundred and twenty-one cases of cataract observed at La Charité there were sixty-one men and sixty women ; while at the Hotel Dieu, out of two hundred and seven patients, there were only seventy-two women, while there were one hundred and thirty-five men. Before the age of thirty years, acquired as well as congenital cataract is almost always soft or capsular. After sixty, it is almost constantly solid and lenticular. The period from forty to sixty years is that which is most liable to it. Between fifteen and forty years, we must be on our guard, for it often indicates a more profound disease of the eye. Although out of seventy-two cataracts examined under this point of view by M. Maunoir, (*Lancette Franc.*, t. I., p. 392,) thirty-five only had commenced in the right eye ; this eye, according to my observation, is more frequently affected the first than the left. I have met with five patients who, from different causes, had been suddenly seized with it, like the peasant mentioned by M. Wendelstrum, (*Thèse citée*, p. 29.) In twenty cases out of two hundred it has appeared to me to be hereditary. A man whose two elder brothers, a sister, his grandfather, and great grandfather had had the same misfortune, was seized with cataract at the age of forty-two years. M. Maunoir (*Thèse citée*, p. 21) states that out of thirty-nine cases of cataract he found ten that were hereditary. In the same family at Argentan, (Duval, *Thèse*, Paris, 1830,) four of the daughters and the father and mother were attacked with this disease. But all this should not prevent us from recurring to the operation.

VIII. *Single or double*.—When the cataract occupies one eye only, there are physicians who proscribe the operation. With one eye, say they, we can see sufficiently well to get along, distinguish objects,

read, and, in fine, fulfil all the duties required of us by our social wants. The operation may produce an acute inflammation, render the sound eye itself diseased, as M. J. Cloquet has seen, and produce a complete blindness. Even upon the supposition that it does succeed, the focus of luminous rays being no longer the same in both eyes, there necessarily results from it a discordance, followed with confusion of vision, &c. To this reasoning it may be objected that if the sound eye is sometimes destroyed after the operation, this accident rarely happens; that we see undisputably better with two eyes than with one only, and that the presence of one cataract appears to be good grounds for supposing that another may supervene upon the opposite side. As to the difference which it is supposed will take place in the field of vision after the displacement or extraction of the crystalline, experience has now demonstrated that it is not the fact. Maitrejan, St. Yves, Wenzel, &c., relate cases in which no mention is made of it, although the patients had been operated on in one eye only. I have published some facts of this kind, collected at the Hospital of Perfectionnement. M. Luzardi writes me that he possesses a great number of similar instances, and I could myself, at the present day, add near fifty cases to those which I announced in 1826. Nor, finally, has M. Roux, who has very often extracted the cataract, found, though it existed on one side only, that it was necessary for the patients afterwards to wear glasses of different forms for the two eyes. Therefore, if the patient is young and of good constitution, if he desires or earnestly requests to be cured, we ought to subject him to the operation, even though one of his eyes may be wholly sound.

IX. *Maturity of the Cataract.*—Formerly it was supposed that cataract passed through different degrees of consistence; that soft and diffuent in the beginning, it becomes gradually firm and solid; in a word, that it may be *ripe* or *not ripe*. At the present day science is under the empire of more correct opinions. It is now known that cataract may be very solid at the commencement, and become almost liquid after a long lapse of years. It is nevertheless true, that the contrary is very frequently observed, and that the idea of maturity and immaturity is not altogether destitute of foundation. Cataract being almost constantly the result of a morbid action from some internal cause, is not in reality perfected until at the moment when this cause ceases to act on the eye, and when the opaque body is no other than a *necrosed* portion of the organism, and an actual foreign body. It is not, therefore, because it is too soft or too hard, that we ought to wait for its complete development; but because its progress not being limited, there are then evidently less chances of success than at a more advanced epoch, and when its separation (coction) has been perfectly effected.

X. *The two Eyes.*—Scarpa, Dupuytren, and many other skillful surgeons have maintained that it is better when the cataract exists in both eyes, to perform the operation first on one side, and not to have recourse to the other until after the cure of the first. If it succeeds, the patient may rest satisfied with it, so long as the eye is not too much enfeebled. If it fails in its results, there still remains at least one more resource. The patient bears the second operation with more courage and less alarm than the first. When we operate on

both eyes at the same time, the inflammation may be communicated from one to the other, the reaction must be more acute and the danger of accidents supervening greater than when we operate on one eye only. Boyer and Dupuytren have remarked on this subject, that double ophthalmia when once developed, rarely fails of arresting itself definitively on one eye only, which takes upon itself, so to speak, the onus of the disease of both, and in most cases ultimately becomes destroyed. The whole of this is questionable; and as the simple operation, even in the most fortunate cases, only imperfectly reestablishes the sight; as patients much rather prefer to sustain the two operations consecutively, than after a certain interval of time; as the operation on one side sometimes causes inflammation of the sound as well as diseased eye; and as the double operation presents numerous favorable chances for one of the two eyes at least, if not for both, I conclude, with Wenzel, Demours, Forlenzi, Boyer, &c., that all other things besides being equal, it is better to adopt this last course.

XI. The *preparations* that the ancients caused their patients to submit to, are almost wholly laid aside by the moderns. At the present day, we limit ourselves to the employment of a regimen more or less rigid during the space of several days; bleeding, some laxatives or a gentle purgative; diluent drinks or antispasmodic and anodyne preparations, according as the patient exhibits certain indications of plethora, obstruction in the alimentary passages, or too great a degree of nervous irritability. As a preventive means of inflammation, there are some who apply a blister. Scarpa places it upon the nape fifteen days beforehand, and M. Roux only the evening before. Forlenzi prefers placing it upon the arm. I am not certain that this application is not more dangerous than useful. Many practitioners dispense with its use, and do not appear to have had cause to regret it. If adopted as a general precept, it must frequently do harm. During the first days, it sometimes produces a heat in the skin, and an irritation which may react in an unfavorable manner upon the eyes. If we confine ourselves to placing it upon the neck, it would then be better to follow the rule of Scarpa, or of Dupuytren, who, when he thought proper to make use of it, left it on fifteen days before proceeding to the operation. On the arm it is evident that the patients can receive no disadvantage from it; nor can we perceive that it can have the least degree of efficacy. For myself, I use it only after the operation, upon the supposition that special accidents require its employment, and I have not found that there were any objections to be made against this mode of proceeding.

XII. *Seasons*.—Spring and autumn, which are more favorable than winter or summer for the success of all operations, have been selected also for those of cataract. We cannot undoubtedly refuse to those two seasons some advantage to the patients, in consequence of the temperature, which is usually more mild and uniform than at other periods of the year; nevertheless, as these conditions may be obtained or found at any time, cataract may in fact be operated upon at any season. We ought not, however, to decide upon it without caution, if an epidemic of a somewhat grave character should be prevalent, especially those which more particularly affect the mucous membranes. When there are prevailing catarrhial affections, doth-

enteric fevers, ophthalmias, measles, or even erysipelas, prudence requires that we should refrain from it.

*C. Operation for Cataract by Depression.*—In some cases we confine ourselves to displacing the crystalline, or placing it under such circumstances, that it may disappear under the influence of the action of the organism; in other cases, on the contrary, we expel the cataract from the eye, in endeavoring to remove the opaque body in its totality, which constitutes two general methods, that of depression and that of extraction. The first, still known under the title of the method by *depression*, comprises, moreover, the method by reclination (*réclinaison*), or *reversion*, or that by discision (*discision*), or breaking up (*broiement*), and is performed in different ways; it takes the name of *scléroticonyx* for example, when in order to reach the crystalline the needle is directed upon the sclerotica, between the uvea and the vitreous humor, or when we purposely penetrate through the hyaloid substance; and it is called *kératonyxis* when we reach the eye in its anterior chamber, through the transparent cornea.

*I. Preceding steps.*—The evening before the operation, the patient, who should have taken only light soups, ought to have administered to him an injection, if his bowels are not already free. An aqueous solution of the extract of *belladonna* applied between the eyelids an hour or two beforehand, forces the pupil to dilate itself largely, enables us to follow with the greatest degree of certainty all the movements of the needle, to avoid the iris with greater facility, and more readily to compel certain portions of the cataract to pass into the anterior chamber, should that be judged necessary. The irritation which such an application produces, is too trivial to be worthy of consideration. The momentary mydriasis which results from it soon disappears, and alters in no respect the functions of the organ. The advantages which it gives are in reality of the highest degree of importance, and should not be sacrificed to idle fears. In irritable and timid persons, in whom the eye is very movable, it is well in order to accustom this organ to the contact of foreign bodies, to touch it several times during the space of some days, with the blunt extremity of any instrument whatever, or even with the finger.

*a. The articles* comprise two needles at least, in order that if one should fail, we may continue the operation with the other; a cap or serre-tête, which should accurately embrace the cranium; a long compress to cover the sound eye while we are operating on the other; small oval pieces of fine linen, perforated with holes, and which are to be placed in front of the orbit after the operation, in order to prevent the lint from coming directly in contact with the lids; a bandage of linen folded double, sufficiently long to go round the head, four to five fingers' breadth in width, and presenting at its middle portion, near its free border, the division of a **J** reversed, to lodge the nose; finally, a band of black taffeta designed for covering the preceding; lastly, a fine sponge, hot water and pins.

*b. Needles.*—As it is more especially for extraction that the *speculum*, elevators and *ophthalmostats* have been proposed, I shall say nothing of them in this place.

As to the needle, we have an infinite variety of them. The one

that Celsus recommends was spear-shaped, straight, and two inches long; at a subsequent period, it was found more convenient to make use of those that are round; since then the triangular needle has been revived. At the present time, every oculist, so to speak, has his own. That which Scarpa succeeded in rendering popular, slender, and only eighteen lines long, is terminated by a point slightly widened, curved into the shape of an arc, flat on its convexity, and cut into a ridge on its concavity, and like all the others, mounted upon a handle of flat sides and bearing a mark of a different color on its back. *Dupuytren* rejects the kind of crest which is found on the concave surface of the needle of Scarpa; his, on the contrary, is somewhat more flat on this side than on the back, in order more accurately to embrace the crystalline, and to expose it less to be divided when we endeavor to depress this into the bottom of the eye. He also recommends that it should have less breadth, and that its body, slightly conical, should completely fill up the track traced by the point, in order that the humors cannot in any degree flow out during the operation. The point of that which is adopted by *M. Bretonneau*, is shorter and also as broad as in the needle of Scarpa. Its body, which is of melted steel, finer and almost cylindrical, passes freely and without the least effort through the opening into the sclerotica. It is an advantage which the instrument of *Dupuytren* does not possess, but one which exposes the eye to be partially emptied of its aqueous humor. The needle of *Beer*, which many German oculists make use of, is straight and spear-shaped, and differs from that of *M. Bretonneau* only in having its body conical and thicker. *Hey* proposed one which has only ten to twelve lines in length, and which in its form approaches much nearer to a chisel than that of a needle; being a simple modification of that of *Hilmer*, which is conical, its free extremity, which is flattened and terminated in a half moon, is its only cutting portion; the edges, which are straight and rounded, and its want of a point, make it difficult to wound the iris when we are directing it towards the pupil, while its form of that of a small palette renders the depression of the crystalline less embarrassing. With an instrument of this kind, it would be almost impossible to destroy a membranous cataract, or even to open conveniently the anterior capsule in lenticular cataract, and inasmuch as the breaking up of the lens to which the author specially designed it, can be perfectly well accomplished with any other needle, there is no reason why it should have the preference. *MM. Graefe, Langenbeck, Himby, Schmidt, Spitzac, (Fascicul. d'Obs., &c., p. 22, Paris, 1829.) Middlemore, &c.*, have also each in their particular way modified the cataract needle. But the difficulty does not lie here. In the hands of a skilful operator, all these instruments are good. In this respect those of Scarpa, Dupuytren, and *M. Bretonneau* are quite as good as any of the others. The needle designed by *Guerbois, (Journ. des Conn. Méd., t. I., p. 250.)* with a double rest on its concavity, does not present sufficient advantages to be retained. *M. Bergeon* has proposed one which two lines in breadth, and hollowed out in the form of a small spoon, would in my opinion be of dangerous employment; although it renders the displacement of the crystalline sufficiently easy. If the needle which *M. Charrière* has shown me,

and which when once in the eye opens itself in the manner of a lithotome of F. Côme, did not expose us to the danger of wounding the iris, and of entangling itself in the neighboring tissues, it might possess some advantages. The one which I prefer is somewhat more incurvated and more flattened, without being less in length or much broader than that of Dupuytren.

II. *Sclëroticonyxis*.—Up to the eighteenth century, they caused the patient to be seated astride a bench. Barth and Arnemann prefer that he should be standing. Poyet, A. Petit, and Dupuytren, advise that he should be operated on in bed. In France, the patient is generally placed upon a solid chair of moderate height. Beer recommends a stool, and Richter a chair with a perpendicular back, while in England they give the preference to a music stool. In this respect there can be nothing fixed. Though the seated position is evidently the best, the others may also be adopted without serious inconvenience.

a. *Ordinary process*.—The surgeon places himself in front, either on the same bench with the patient, whose knees he holds between his thighs, as in the time of Celsus, with a small cushion to support his elbow, as recommended by J. Fabricius; or he stands up, as Dupuytren and a great number of others advise; or he seats himself on a chair somewhat elevated, in such a manner as to be able to place his foot upon a stool, and to support his elbow upon a cushion on his knee, as directed by Scarpa. When seated, there is more fixity in his movements, since the elbow is supported; when standing up he is more free and more at his ease. Some surgeons separate the eyelids themselves, and dispense with assistants. Barth never operated otherwise. In this respect there has been much praise bestowed upon the skill of M. Alexandre, who again, it is said, is surpassed by Dr. Joeger in Germany. The thing doubtless is possible, but exhibitions of force cannot be taken as a rule, and there is no operation in surgery which more requires an intelligent assistant, than cataract. It is necessary that he should have a light hand, that he should perfectly comprehend every stage of the operation, and all the movements of the operator, and that he should be as practically conversant with it as possible. Being placed behind the patient, he embraces the head, and holds it against his chest with one hand, while with the other he elevates the upper eyelid. Should we desire to have recourse to any instrument to open the eye, the double erigne of Bérenger, or the blunt hook of some others, could evidently be replaced by Pellier's elevator of silver wire. In general the finger is preferable, whether with Scarpa, we make use of it to raise and to keep up the free border of the upper eyelid against the supra-orbital arch, without touching the eye; or whether after the manner of Boyer, we push it (*l'enfoncé*) against the posterior surface of the superciliary border, while incurvating its last phalanx in the manner of a hook. By this last mode, the eyelid is found to be more firmly fixed; but the angle formed by the phalangeal articulations, causes more inconvenience to the operator, and the eye runs more risk of being compressed. Forlenze was in the habit of causing the entire tegumentary covering of the eyelid to be drawn towards the eyebrow, as if for the purpose of folding it or forming a border with it

there. In this manner the ciliary border, or tarsal cartilage, is raised as high as possible, and the pulp of the finger leaves less facility for the skin to escape. The most certain means of preventing our losing our hold before it is time, consists in placing a piece of dry linen between the finger and the integuments, in order to prevent them slipping over each other. If the patient is in bed, the surgeon places himself on the right for the left eye, and on the left for the right eye; adjusts the cap and fixes it with the bandage; covers one of the eyes, whether it is diseased or not, with a small piece of coarse lint, and a long compress passed obliquely round the head. The assistant, free or raised on a chair at the head of the bed, prepares for elevating the eyelid.

*First stage.*—With the forefinger corresponding to the diseased side, the operator depresses the lower lid and fixes the eye. With the other hand he seizes the needle in the manner of a writing-pen, directs its point perpendicularly upon the sclerotica, at one or two lines from the transparent cornea, a little below its transverse diameter; turns its concavity downwards, one of the cutting edges towards the cornea, and the other towards the orbit, in order that he may penetrate, rather by separating apart, than by dividing through, the fibres of the coats of the eye; first inclines the handle of the instrument with a considerable deal of force downwards, then raises it gradually in an opposite direction in proportion as he enters into the posterior chamber, and makes use of his two last fingers in order to procure a point d'appui, between the parotid and the cheek bone.

*Second stage.*—Before plunging it in farther, he turns the instrument upon its axis, in order that its concavity may face backwards, and that he may be enabled to pass without danger below, then in front of the crystalline, while penetrating from without inwards and slightly from behind forwards, without touching the iris or lenticular capsule, if he possibly can, as far as into the pupil and anterior chamber. He then passes its point circularly several times around the anterior circumference of the lenticular body, the envelope of which is in this manner lacerated as completely as possible.

*Third stage.*—This being accomplished, the surgeon applies the arc of the needle directly upon the front part of the cataract, which he then draws by an oscillating movement downwards, outwards, and backwards, into the bottom of the eye, below the pupil and the vitreous humor, where he holds it fixed for the space of a minute, in order that it may not become disengaged.

*Fourth stage.*—The instrument is then drawn back without shaking it, by small movements of rotation; it is brought back to the horizontal position; we again turn its convexity upwards, and remove it from the eye, by making it pass through the same track it had taken in entering.

*Remarks on the preceding different stages.*—Many points in this operation require particular attention.

1. To make use of the *right hand*, for the right as well as the left eye could be of use only to those surgeons who are not ambidexter, and it is not often that these latter venture to perform operations on the eyes.

2. If the *needle* were directed *above the transverse diameter* of the

sclerotica, as some practitioners, and among them M. Pilson, have recommended, it would become almost impossible to depress the crystalline completely, or to avoid leaving it more or less near the centre of the eye. In applying it exactly upon the external extremity of this diameter, we should be certain to wound the long ciliary artery, and to produce an internal hemorrhage. It is below it therefore that we must apply it. When its convexity is turned forward, as Scarpa recommends, the fibres of the sclerotica, as well as some of the ciliary nerves and vessels, are necessarily divided, whereas nothing like this takes place if we conform to the precept which I have laid down.

3. J. Fabricius laid it down as a rule that the *needle ought to be plunged in at the union of the sclerotica and cornea*. Others, with Purmann, say at half a line from this last; some at a line and a half; several at two lines, two lines and a half, and even three lines; there are those who say the breadth of the nail or of the stalk of a straw, the middle of the white of the eye, &c., and those who are in favor of going as distant as possible from it, are influenced by the fear of wounding the ciliary circle or processes. Among others, there are those who, like Platner, apprehend the lesion of the tendinous portion of the rectus externus muscle or the nerve of the sixth pair. Fabricius, in approximating the cornea, specially designed thereby to reach more directly in front of the cataract, while the majority look only to avoiding with greater certainty the retina. As to the fact itself, two things appear to me indisputable: it is that the puncture of the fibrous expansion of the rectus muscle involves not the slightest inconvenience, and that that of the retina is unavoidable when we penetrate through the sclerotica, at whatever distance it may be from the cornea; from whence it follows, as a general rule, that there is no danger in receding from, while there would be in approximating too near to the ciliary body.

4. In turning *the back of the needle forward*, when we wish to pass it below and then in front of the cataract, and to conduct it in this manner in the anterior chamber through the pupil, our object is to protect, with as much certainty as possible, the retina and the iris from the action of its point or cutting edges. If we work with it in the anterior chamber, it is in order to be more certain that it may not work between the lens and its envelope. The laceration of this last is a more delicate and important operation than is generally supposed; it is upon its circumference that we must commence. If we pierced it first at the centre, it would be very difficult afterwards to detach the flaps from it, and to prevent the formation of a secondary cataract. The best mode undoubtedly would be to depress at once both the crystalline and its capsule, without breaking them, as some authors have recommended; but by what mode could we force a membrane so delicate to the bottom of the eye without dividing it, provided that its adhesions have retained some degree of firmness?

5. It is not sufficient, in order to depress the opaque body, to seize it with the point of the needle. The *concavity of the instrument* ought moreover to embrace exactly and flatwise its anterior surface at its middle portion, from the inner side of the pupil as far as to its outer portion; otherwise it would be reversed upon the slightest de-

gree of pressure, either from above downwards or from below upwards. The depression having once commenced, the needle represents a lever of the first kind, which finds its point d'appui in the opening of the sclerotica, and which, in order to make resistance outwards, backwards and downwards, should have the concavity of its point slightly inclined upwards, while we give to it the oscillatory movement mentioned.

6. *When the cataract is depressed*, it is recommended to the patient to look upwards and inwards without moving the head, supposing by that, but erroneously, that the crystalline would be made to descend lower down. In not withdrawing the needle until at the end of some seconds, time is given to the depressed cells of the vitreous humor to resume their natural position, and to imprison, so to speak, the cataract, which would almost mount upwards if we left it immediately. The small movements of rotation which the instrument is made to perform before disengaging it from the eye, have evidently for their object to disturb the crystalline as little as possible, and to be more certain of leaving it in its new locality.

7. If, notwithstanding all these precautions, the cataract mounts upwards again as soon as we cease to keep it depressed, we must seize it a second time and depress it farther down, and continue in this manner until it rises up no longer.

8. *When it is soft* the instrument ruptures it, and we rarely succeed in entirely depressing it below the pupil; in such cases, if it is not practicable to displace its fragments backwards, we endeavor to break it down into small particles, which are to be pushed forward into the anterior chamber, in order that their solution by the aqueous humor may prepare them for absorption. It is also to this place that we must direct every opaque particle which may be found to remain in the centre of the eye after the displacement of the crystalline. The foreign corpuscles are in this manner easily pushed forward in front of the pupil, provided they are completely liberated. Unfortunately the case is not the same, when our design is to place there the flaps from the crystalline envelope. In this case we must have skill and address to transfix, so to speak, each flap in succession, from before backwards or behind forwards, with the point of the needle near the centre of their base, and to detach them while rolling them up upon themselves, or by drawing them on the side near their apex. If the capsule adheres to the uvea we ought, before all other things, to effect its separation, and in doing this avoid the iris as much as possible. Upon the supposition that some circumstance may occur to prevent this disunion, we should necessarily be obliged to displace the crystalline at first, and act afterwards upon the anterior layer of the capsule, as has been described above.

9. *Crystalline in the Anterior Chamber*.—The cataract, at the moment of the operation, may, in consequence of some sudden movement of the patient or the operator, escape through the pupil and fall into the anterior chamber. This may also happen spontaneously from various causes, as blows, falls, sudden strokes, and anything which may concuss the head of the individual, or in any manner bring about the rupture of the lenticular cyst. This circumstance does not necessarily oblige us, as has been supposed, to resort

to the extraction of the displaced disc. Inasmuch as it has gone through the pupil, in order to place itself in front, it could traverse it again to get behind, and it will always be found more agreeable, both for the patient and the surgeon, to terminate the operation while the needle is in the eye, than to withdraw it again in order to incise the cornea. In the cases even where nothing yet has been attempted, it is no obstacle to depression, provided the pupil remains dilatable and that there is but very little degree of inflammation. Dupuytren and M. Luzardi, who, under such circumstances, have made use of the ordinary needle, have plunged it through the sclerotic and pupil into the anterior chamber, in such manner as to seize hold of the lens, whether opaque or not, and which they have afterwards succeeded in conducting into the bottom of the posterior chamber. I have frequently noticed this accident, but it never has appeared to me of serious character at the moment of the operation. There are, moreover, some singular facts in relation to this subject. In a patient of M. Monod the crystalline remained in the anterior chamber. This woman, having left the Hospital of Cochin, came to the clinique two months afterwards. I then noticed that the crystalline occupied its usual place in the posterior chamber.

Having left my service at the expiration of six weeks, the patient came back again three months subsequently, when the crystalline was again found in the anterior chamber, having vessels which appeared to have penetrated into it, and where, being now reduced to a third of its volume, it appears to constitute a part of the cornea! In another case the crystalline having passed into the anterior chamber several months after depression, repassed into the posterior chamber while Pellier (*Gaz. Salut.*, No. 50, p. 4, col. 2, 1760,) was dividing the cornea in order to extract it.

10. In *milky cataract*, if as almost always happens, the capsule itself is affected, it is almost indispensable to carry the instrument as far as to the centre of the pupil without dividing anything, otherwise the opaque liquid diffuses itself into the eye, renders the humors turbid, and prevents us from any longer seeing what we are doing. Nevertheless should this accident happen, and whether the needle was or was not in the anterior chamber, we ought before withdrawing it, to simulate as accurately and with as much caution as possible, the manipulations necessary to break down whatever it might be necessary to destroy.

11. *Purulent cataract*, of which I have seen two very marked examples, would require no additional attentions, as its absorption is also speedily accomplished.

12. If, as I have often seen, the cataract should, on the contrary, be very *hard*, stony, cretaceous, or like *tupha*, (tophacée,) which is recognized by its unequal, ridgy, and white or yellow calcareous color, we should treat it in the same manner precisely as an ordinary crystalline, except that its capsule being folded and retracted, and, as it were, parched up, cannot be isolated from the rest, and must be depressed with the same stroke. Should the cornea, (Darcet, *Thèse citée*,) the crystalline, (Kulm, *Chir. des Hopit.*, t. III., p. 397,) or vitreous humor (Middlemore, *Revue Méd.*, 1838, t. III., p. 269,) be ossified, any operation doubtless would be useless.

*b. Other Processes.*—1. *Process of Petit.*—At the commencement of the last century, some authors sustained, contrary to Hecquet, de la Hire, &c., that the seat of the cataract was always in the crystalline. Petit, adopting this hypothesis, proposed to accomplish the depression of the opaque body without touching the anterior layer of the capsule. After having plunged the needle into the posterior chamber, he inclines one of its cutting edges outwards and backwards; opens into the vitreous humor in this direction; brings the needle back to the outer, lower, and posterior part of the capsule, which he ruptures, secures the crystalline by hooking into it, and passes it into the substance itself of the hyaloid body, while conforming in other respects to the general rules for depression. *This modification*, revived some years subsequently by Ferrein, who declared himself the inventor of it, was afterwards supported by Henkel, Gunz, Gentil, Walsbom, &c. In allowing the anterior capsule to remain intact, it was to reëstablish the vision more completely than by the ordinary process. It was maintained that in falling upon a convex membrane the luminous rays would scarcely feel the loss of the crystalline: that the concordance of the focus of vision would be preserved; and that we should not in fact be under the necessity of using spectacles after the operation. To these reasons, practitioners objected that the capsule is frequently itself the seat of cataract, either alone or conjointly with the crystalline; that more often still it becomes opaque afterwards, and produces a secondary membranous cataract, should we fail to destroy it at the time of the operation; that consequently, so far from preserving it, we ought to endeavor to break it up as thoroughly as possible; finally, that in depositing the crystalline exclusively in the vitreous humor, in place of simply depressing it into the posterior chamber, we should run the risk of producing serious accidents.

2. *Process of the author.*—The last objection raised by the adversaries of Petit is the only one destitute of foundation. If the laceration of the vitreous body were dangerous, the operation for cataract by depression would scarcely ever succeed, for it is almost impossible to be avoided. Should not the crystalline enter, to some extent, in spite of the operator, into the vitreous humor, can it be supposed that it would ever remain depressed, pushed back as it continually would be by the natural elasticity of the hyaloid membrane? Moreover, in causing it to glide between the coats and humors of the eye, how could we avoid lacerating the retina? Proceeding upon this idea, M. Bretonneau has deemed it advisable to adopt the process of Petit by modifying it; that is to say, that in place of opening the capsule posteriorly, this surgeon, after having traced out a passage for the crystalline into the vitreous humor, proceeds to the rupture of the capsule in front as by the ordinary process. Being a witness of the successes obtained by this process at the Hospital of Tours, in 1818 and 1819, I have adopted it without having had any reason to regret it. I perform it in the following manner: the needle is directed as if to pass behind the cataract; when it has arrived at about four lines of depth, before changing its position, we incline it downwards, backwards, and outwards, in order to open into the anterior cells of the vitreous humor; immediately afterwards, we turn its back towards the iris; then while ele-

vating its handle, we cause its point to pass under the lower border of the crystalline, that it may afterwards be conducted into the pupil; then lacerate the anterior layer of the capsule; seize the opaque body, and push it by a well regulated vibratory movement, in the direction of a line which would extend from the great angle of the eye to the mastoid process on the same side. We thus avoid wounding the iris; the elasticity of the vitreous humor, though sometimes quite considerable, cannot however offer the least degree of resistance, and enables the cells of its membrane, while immediately closing the passage, to become an obstacle to the reascension of the crystalline.

3. *Another process.*—I have often also employed another process which has appeared to me to be very convenient. In place of inclining the needle downwards, I direct it upwards, and from behind forwards, in order to bring it above and in front of the crystalline, and into the pupil. By this means we more completely detach the cataract, and nothing is more easy afterwards than to force it backwards and downwards.

4. An itinerant oculist, *M. Bowen*, has published a method which he calls *hyalonyxis*, and which appears to him preferable to every other. His object is to traverse the vitreous humor from behind forwards, then to lay open the posterior layer of the capsule, and to detach the crystalline after the method of Petit or Ferrein, without interfering with its anterior envelope. For that purpose *M. Bowen* pierces the sclerotica at four lines from the cornea. The results of his practice are all in favor of *hyalonyxis*, for he scarcely counts two failures out of twenty operations. From this therefore we may at least conclude, that the wounding of the retina and the vitreous humor is a matter of very little consequence. I do not see, moreover, any advantage in going so far from the cornea, and there is no necessity of recalling the inconveniences to which we are exposed in not destroying the anterior layer of the capsule. Nothing moreover would prevent our avoiding it, if we desired to do so, by the process which I have adopted.

5. *M. Ruete*, (*Gaz. Méd.*, 1838, p. 677,) in causing his needle to penetrate at the *side of the capsule* on a line with the pupil, then turning the point of his instrument forwards, in order to rupture the envelope of the crystalline, and proceeding afterwards to the depression of the cataract, has in this process done nothing more than what often happens to other surgeons without their being aware of it.

6. *M. Goyrand* plunges his needle into the vitreous humor from behind forwards like *M. Bowen*, and immediately causes it to perform a circular movement upon the whole circumference of the crystalline, which latter he transfixes in order to drag it into the vitreous humor, without paying any attention to the anterior capsule. I have seen him operate in this manner with great rapidity.

7. *M. Gensoul* formerly made use of a process, which he soon after abandoned, but which *M. Roux* has since thought proper to make trial of at Paris, and the idea of which seems to belong to *B. Bell* or to *M. Giorgi*. A small incision is first made behind the iris, at the union of the sclerotica with the cornea. The surgeon introduces through this opening, a sort of scoop to the fore part of the

crystalline, which he pushes down or depresses, and the operation is thus terminated. The only advantage from so large an opening of the sclerotica, would be in giving relief more easily than by a simple puncture to the too great degree of fullness of the eye, (*trop plein de l'œil.*) But the division of the ciliary body, the possible escape of the humors, and the impossibility of carrying the cataract sufficiently far backwards, would of themselves suffice on the face of them to cause this process to be forever proscribed, though even the trials of its inventors and of M. Roux, did not come to our assist- to demonstrate its inconveniences and dangers.

8. *Reversion or Reclination.*—Since the time of Pott, some authors, among others Willbourg and Schifferli, have maintained that in place of depressing the crystalline, it would be better to effect its reversion. We cannot deny that this modification would render the operative process both more simple and more easy. When the needle has lacerated the anterior capsule, all that is necessary is to apply it a little nearer to its superior than to its inferior border, in order that by pressing upon it, the reversion of the lens may be effected at the moment by an oscillatory movement, which places its anterior surface above, and its superior border behind. If we desired, moreover, to drag the cataract into the substance, or below the vitreous humor, as Beer, Weller, and others recommend, reversion evidently becomes the usual mode of depression, whereas, if we should abandon it in the posterior chamber, below the centre of the pupil, it is clear that it will in most cases reascend, or that its presence would irritate the iris and the rest of the eye to such a degree as to give rise to accidents. Reversion then, is only a *dernier resource*, and never a process of election.

9. *Discision or breaking up.*—Pott, after having endeavored to demonstrate that the crystalline, when it is once placed in immediate contact with the aqueous humor, is dissolved, and ultimately disappears, wished also to prove that it is not indispensable to depress it below the axis of vision; that it is sufficient, as Warner had advanced, to reduce it into fragments; that in fact, as Ware pretends, a cure may be effected by rupturing its capsule. Experience has occasionally confirmed this opinion, for the examples of solution and absorption of the crystalline, whether it was left entire or broken up into fragments, are not uncommon. As on the other hand, the breaking up of the crystalline relieves us of the most difficult point of the operation, it is very natural that M. Cappuri, (Paccini, *Bull. de Férussac*, t. XIV., p. 192,) as well as many other oculists, should have adopted the opinion of M. Adams, who recommends that it should be made use of in all cases. Nevertheless, I will say of this the same thing that I would of reversion. It is a process which is to be adopted when the cataract is soft or too difficult to be displaced, but it is one which, notwithstanding the eulogiums bestowed upon it by M. Parmi, is less certain than depression properly so called. If it is true that the fragments of the crystalline are sometimes dissolved with sufficient rapidity, it is also true that very frequently they remain there for months, and even to an indefinite period, and in such way as to prevent the re-establishment of vision. If the wounding of the vitreous humor is thereby less difficult to be avoided, that of the

iris is ordinarily more so. Upon the supposition that there might be some advantages in leaving the cataract to be gradually absorbed, they will be found more than counterbalanced by the anxiety of the patient, and the loss of time which must elapse between the moment of the operation and the period when the pupil is again restored. I am still less capable of comprehending M. Lowenhardt, (*Gaz. Med.*, 1838, p. 812,) who has had the temerity to pass a seton through the crystalline in order to cure the cataract, and who declares that he succeeded! All the needles are good for effecting discision. That of Beer, or M. Lusardi's small needle, in the form of a sickle, seem more convenient, however, than those of Hey and Dupuytren, and even than those of Scarpa and M. Bretonneau. Although we may break up the crystalline by attacking it on its posterior surface, it is, nevertheless, preferable to act upon its opposite surface, in order that we may be better enabled to see what we are doing, and to be more certain of avoiding the iris. In this mode, when the instrument has once arrived in the pupil, and that the capsule has been properly ruptured, we direct its point and one of its cutting edges upon the middle of the cataract, which latter is divided at first into two parts, in order to return upon each fragment separately, in order that they may be reduced into as small particles as possible, after which we endeavor to push the largest of them into the anterior chamber, by means of the back of the needle. When we operate from behind forwards, and employ the straight needle, the breaking up of the lens is in reality more easy, so long as the anterior layer of the capsule remains entire, because the crystalline being then shut up as it were in a sac, and unable to escape, is compelled constantly to present itself to the action of the instrument; but the vitreous humor suffers much more than by the other process, and it is very rare, moreover, that the lens and its envelope are not pierced through and through at the very first movements.

III. *Keratonyxis*.—Depression, reversion, and broiement, which are generally performed, as we have just seen, by scleroticonyx or by sclerotico-hyalonyxis, are also accomplished by keratonyxis, that is to say, by penetrating through the transparent cornea. This process, whose invention has been disputed by many moderns, is far from being new. Avicenna speaks of practitioners who first opened the cornea and penetrated by that means to the crystalline, which they afterwards depressed by means of a needle that they denominated *al-mokadachet*. Abu'l-Kasem asserts positively that he adopted this method, and that when the needle is plunged into the crystalline, some gentle movements are required to be made upon it in order to depress the cataract. M. Herbeer (*Carron du Villard, Oper. de la Cat. &c.*, p. 11, 239,) affirms that this has been the practice in Egypt from immemorial time, and M. Souty, (*Ibid.*, p. 241, 1834,) makes the same remark of the medicastres of India. Manger also relates the case of an English woman, who cured cataract by piercing the cornea. In the collection of Haller, we find a thesis supported by Col. de Vilars, under the presidency of Le Hoc, in which this operative process is much extolled.

It is in this manner, says the author, that birds recover their vi-

sion by plunging a thorn into the eye, and it is thus, according to Galen, that goats have pointed out to man the manner of operating for cataract. In the 18th century, Smith had already revived the process of the Arabs. Dudell, the disciple of Woolhouse, considering cataract almost always membranous, proposes that we should penetrate the cornea to reach the anterior capsule, and to remove from it a circular disc by means of the needle, in such manner as to form there a sort of window to give passage to the rays of light. The famous Taylor and Richter frequently performed keratonyxis in cases of milky cataract. Gleize in France, and Conradi in Germany, made it known in the year 1786. In 1785, Beer had performed it twenty nine times. Demours had performed it in 1803, the epoch at which Reil had endeavored in his lectures to call attention to it, and when he gave it the name which it bears. But it has required no less than the united efforts of Buckhorn in 1806 and 1811; Langenbeck, in 1811 and 1815; Dupuytren, Guilié, and Walther in 1812; Wernecke, in 1823; and Textor and Pugin in 1825, to assign it a place among regular operations.

*a. Operative Process.*—The patient and the assistants are placed in the same manner as for scleroticonyxis; the surgeon directs the point of a curved needle, that of M. Bretonneau, for example, or that of M. Langenbeck, which, though more pointed, has a cutting edge of less extent, at about a line from the sclerotica; supports the back of it upon the finger which depresses the lower eyelid; causes it to penetrate into the anterior chamber at the lower or external part of the cornea; arrives in the pupil; then turns downward the concavity of his instrument, which up to this moment he had held in an opposite direction in order to avoid the anterior surface of the iris; freely lays open the capsule; detaches the crystalline; hooks its upper border; depresses and reverses it; endeavors even to push it below the pupil into the vitreous humor, or what is better, comminutes it, and breaks it up and depresses its principal fragments when he cannot bring them into the anterior chamber; and afterwards turns the back of his needle downwards again, and withdraws it by making it pass through the same track in an opposite direction to that by which it was introduced.

*b. Appreciation.*—Keratonyxis should not be attempted until we have previously produced a sufficiently extensive dilatation of the pupil, the borders of which nevertheless it is very difficult in spite of this precaution, to avoid wounding severely, when we are endeavoring to depress the crystalline. It is to obviate this inconvenience, and especially in order not to puncture the iris, that straight needles among us have generally been proscribed, and that we penetrate at some distance from the sclerotica, taking care at the same time not to approximate too near the centre of the cornea. The pyramidal needle of Beer, the shoulder that M. Graefe has caused to be added to the stem of the ordinary needle to prevent its penetrating too deep, the needle of Himly, and that of Schmidt, &c., do not in reality present any advantage over those which are used in France, and require no further description in this place. In animals this process is preferable to all others, for reasons which it is unnecessary for me to point out. Though in the human species it may in fact be em-

ployed wherever depression is practicable, it is not advisable to make choice of it except for milky cataract, and in children and intractable subjects, and where the eyes are very movable and irritable or deeply depressed. The same hand will answer for both eyes; no nerve or vessel incurs any risk of being wounded. The retina remains intact; nor is the iris in more danger than by the posterior method. The tissues that are traversed have scarcely any sensibility, nor does the membrane of the aqueous humor, which MM. Wardrop, Langenbeck and Chélius appear to have so much dread of wounding, possess any more than a very slight degree of vitality. The operation then resolves itself definitively into a simple puncture, and may be repeated a certain number of times without any serious inconvenience. But to these advantages no less numerous objections may be opposed. The adhesions of the capsule, the contraction of the pupil, the narrowness and flattened form of the cornea, the projection of the iris, and hard gypseous or stony cataracts, do not appear to be adapted to it. Properly understood, it is for the breaking up and reversion of the lens only that we may sometimes have recourse to keratonyxis. Though it has succeeded in seven times out of eight with M. Textor; that in many hundreds of patients, M. Smalz, according to M. Eccard, has never seen it produce suppuration of the eye; that out of 345 cases of M. Walther, he failed only in twenty-six; Dupuytren, in one out of six; and M. Langenbeck, in four only out of 112, this process nevertheless has been abandoned as a general method, by even its warmest partisans themselves. M. Wedmeyer, who has performed it fifty-three times, rejects keratonyxis as well as M. Langenbeck, and M. Schindler, (*Bull. de Fér.*, t. X., p. 352-354,) who prefers in this operation to pass through the centre of the cornea, will not succeed in giving it any great degree of popularity. Nor do I think that M. Pauli, (*Arch. Gén. de Méd.*, 1838, t. III., p. 352,) who, penetrating at the cornea, then divides the vitreous humor above the crystalline in order afterwards to perforate through this opening through the entire body of the lens, will ever succeed in causing his method to be adopted. Nor can I comprehend any better the superiority of what M. Quadri (*Gaz. Méd.*, 1833, p. 643) calls his *mixed method*. How is it possible that a sort of *forceps-needle* introduced through the cornea in order to extract the capsule of the crystalline, while the cataract is being depressed by means of an ordinary needle passed through the sclerotica, could render the operation more simple, more sure and less dangerous? I conclude therefore that keratonyxis cannot be substituted for scleroticonyxis, which alone enables us to push the crystalline without extracting it, outside of the visual axis, and to fix it there securely, promptly and permanently; and that in fact it only deserves a place in books of surgery under the character of an exceptional method.

c. As to the simple *puncture of the cornea*, as formerly practiced by Lehoc, and more recently by M. Wernecke with the view of promoting the solution or absorption of the cataract, it has not yet sufficient proofs in its favor to authorize its being formally recommended. If nevertheless, as cannot be doubted, the decomposition of the crystalline separated from its membrane, is a phenomenon much more chemical than vital, we cannot see why the evacuation of the aque-

ous humor, when once impregnated with the foreign substance, might not favor the dispersion of the cataract, in permitting the liquids with which it is surrounded to be renewed.

IV. *Operation for Cataract in Children.*—In the early period of life, we can scarcely have recourse to the method of extraction. We should rarely succeed in accomplishing it without emptying the eye. As is demonstrated by the observations of Scarpa, Ware, Saunders, Gibson, M. Lusardi, and M. Lawrence, who has seen it in four brothers, &c., congenital cataract and accidental cataract in young persons are almost constantly liquid and membranous. There is consequently but little to do with depression or extraction. The object to be attained is to lacerate as completely as possible, the anterior disc of the capsule, and to empty it of the matters that it contains. In such cases it is a matter of indifference whether we operate by keratonyxis or scleroticonyx, at least when the pupil is very large, a condition which ordinarily exists. The most difficult point is to restrain the little patient. Ware confines himself to placing him upon a table, raising his head by means of pillows, keeping him held down by assistants, and holding the eye steadily by means of the fingers, while another assistant raises the upper lid with the elevator of Pellier. Gibson, who first gives an anodyne potion to blunt the sensibility, causes the most intractable to be imprisoned in a sort of sack, open at both ends, and which is confined above the shoulders and below the feet by means of a running string. Finally, M. Lusardi finds it more commodious to seat the child upon the angle of a prepared table, after having fastened his arms around his trunk and placed his legs between the thighs of the operator. Whether we penetrate through the cornea or the sclerotica, it is always important to effect a complete loss of substance at the anterior disc of the capsule, and not to confine ourselves to its simple rupture, unless we wish to incur the risk of seeing a secondary cataract supervene soon after. If the crystalline should still retain some degree of resistance, and if it should appear that the capsule itself ought to be broken up into fragments, it would become necessary, as in an adult, instead of leaving them in their place, to force them into the vitreous humor or push them forward into the anterior chamber. If at the expiration of fifteen or twenty days, any fragments should remain at the place of the crystalline, Ware recommends that we should repeat the operation, without waiting any longer, and states that he has performed it four or five times successfully in this manner on the same child. Such a course of procedure ought not to be imitated, unless we have satisfied ourselves that the fragments of the cataract have absolutely ceased to diminish in volume. This perhaps would be an occasion for making trial of the process of Wernecke, and of evacuating the aqueous humor by a puncture in the cornea.

V. *Subsequent Treatment.*—When everything is finished after the operation for cataract by depression, the patients are recommended to keep the eyelids gently closed. The practice of placing before the patient some object to ascertain the result of the operation should be abandoned by all practitioners. The light arriving in full force and suddenly into the bottom of the eye, irritates the retina too severely, and such a test in every respect can only be intended to

gratify an idle curiosity. After the employment of the needle especially, it must completely fail in its object, since the disturbance we have just produced in the chambers of the eye may render the sight very confused at first, though it is to be completely reëstablished afterwards. Nobody at the present day would venture to follow the recommendation of Purmann, by applying over the puncture of the sclerotica, a small piece of gold-leaf, with the view of preventing the escape of the aqueous humor or the vitreous body.

Brandy and the white of an egg, employed by the ancients, and a thousand other topical applications lauded without any foundation, are also proscribed. We confine ourselves to wiping out the eyelids with a sponge or a fine compress, then placing in front of them the oval piece of linen perforated with holes, dry or imbued with cerate, and over these a soft compress of lint, and a bandage of linen, which is arrested under the nose by the bridle formed by its notch, and which is fixed behind to the cap by means of some pins; finally, the band of taffeta which is to cover the whole. It is important that none of these portions of dressing should be drawn so tight as to compress the parts contained in the orbit. For myself I confine myself in most cases to the employment of a simple bandeau, which bridles the nose, and which I attach to the cap behind by means of pins. The patient operated upon should make no effort nor any movement. Being carried back to his bed he is to be laid upon his back, with the shoulders and head elevated by means of pillows. The habit of surrounding him with thick and colored curtains, and of allowing but little light to penetrate into his chamber, has appeared to me to be more hurtful than useful. During the space of three or four days we allow him only bouillon or light soups. If the stools are not regular, emollient clysters or even laxatives are to be administered. We may give him also, for example, a drink of a more or less relaxing character, such as whey, barley-water sweetened, syrup of prunes, veal broth, or decoction of tamarinds. However little cephalalgia, heat of skin or febrile movements, may supervene, bleeding is not to be omitted. When nausea and vomiting should at the same time be present, laudanum by injection, as Scarpa recommends, is indicated and produces very good effects. In ordinary cases the usual drink to be employed is infusion of linden, violet or wild poppy, sweetened with some syrup. Loss of sleep and restlessness are to be relieved by an ounce of syrup of white poppy or diacodium made into a julep, which is to be taken by teaspoons full. When no serious accident supervenes we do not uncover the eyes until the third or fourth day; while everything goes on well it is perfectly useless to examine them before that time. Should any accident occur we should be apprised of it by the state of the pulse, the cephalalgia, the pain in the orbit, the running of the tears and the saturation of the dressing by a yellow discharge. To perform the dressing the patient must be first seated. The different portions being removed, a basin with warm water is placed under his chin, and by means of a sponge he himself moistens and separates his eyelids, which he immediately opens after the operator has wiped them. At this time the curtains are to be closed. Even though the pupil should appear to be regular, it is scarcely yet prudent to undertake to ascertain the extent to which the sight

is re-established. The dressing is to be reapplied and renewed every day, and we proceed in the same manner as in cases of simple ophthalmia, while the eyes retain their redness. If everything goes on well we allow at every dressing a little more light to fall upon them, in such manner that at the expiration of twelve to fifteen days they may be left uncovered and protected only by a simple shade of dark taffeta. Nor is there any longer any necessity of the diet being very rigid, and the patient may get up in the course of the second week, resuming by degrees his customary regimen. I have frequently even made them or allowed them to get up at the beginning of the fourth day. Under a contrary state of things, we must look to the kind of symptoms which are developed, in order to employ in good season, antiphlogistics, general or local, purgatives, revulsives, and collyria, of this or that description, in the same way as we would do in a disease of the same kind produced by any other cause, not forgetting at the same time that iritis, retinitis, and choroiditis are under these circumstances the accidents that we are especially to endeavor to prevent or to combat.

*D. Operation for Cataract by Extraction.*—Cataract was still but very imperfectly known, both in respect to its seat and its nature, when it was already proposed to extract it. Antylus, according to Sprengel, opened the cornea by means of a needle, and proceeded to seize hold of the opaque pellicle through the pupil, in order to extract it. Lathyrus operated in the same manner. It appears also that Galen practised incision of the cornea in front of the membranes, in order to extract the cataract. Ali Abbas and Avicenna speak of extraction as a common method. Abu 'l Kasem states that he learned from an inhabitant of Irack, that in that country the practice was to introduce a short needle into the anterior chamber in order to void the cataract. Avenzoar and Isa Ebn-Ali, who reject it, state that in their time it was in general use in Persia. G. de Chauliac himself has not forgotten it; and Galeatius, who extols it greatly, gives himself out as its author. Entirely forgotten, however, or laid aside, by the authors of the middle ages, the operation for cataract by extraction does not appear to have been revived in practice until about the end of the seventeenth century and the commencement of the eighteenth. In 1694, Freytag laid open the cornea in the manner of the Arabs, and succeeded afterwards in extracting from the eye an opaque membrane, which doubtless was no other than the anterior layer of the capsule of the crystalline. Woolhouse passed through the anterior chamber with a needle arranged in such manner as to be susceptible of being transformed at pleasure into a forceps, and which enabled him afterwards to seize hold of the opaque body in order to effect its extraction. Petit, effecting, in the presence of Méry, the extraction of a cataract which had fallen into the anterior chamber, surprised many of the assistants by showing to them an opaque crystalline in place of the pellicle they had expected to see. St. Yves also decided upon extracting the crystalline lens, but without success, which induced him, but we do not see for what reason, to maintain more strenuously than ever that cataract does not have its seat in the body of the lens. These different attempts had then scarcely attracted any attention when Daviel, in 1748, submitted

his method to the judgment of the Academy. By means of a large instrument shaped like the tongue of a carp he opened into the lower part of the cornea; the wound in which he afterwards enlarged by means of a second instrument narrower than the first, or by small curved scissors. A gold spatula to keep the lips of the wound open; a needle of the same metal, which was flat and triangular, for the purpose of opening the capsule, and a scoop to favor the issue of the crystalline or its connections, were also necessary to this surgeon. A crystalline which had fallen into the anterior chamber, had obliged him to put his process in practice for the first time in 1745. One hundred and twenty-two cures out of two hundred and six operations, as announced by him, made a vivid impression on the public mind; and although the Caqué of Reims had mentioned only seventeen successful results out of thirty-four operations, every body, nevertheless, was anxious to repeat his essays. *Pallucci*, who professed, in 1752, to have performed extraction before *Daviel*, opened the cornea from the small to the great angle of the eye by means of a knife, the apex of which being very much elongated, resembled a kind of needle. *Poyet* devised a narrow instrument, pierced near its point in order to pass through this eye a noose or thread, which would be capable of supporting this organ while the flap of the cornea was being made from above downwards. *La Faye* proposed to substitute for all these instruments of *Daviel*, a knife in form of a lancet, somewhat narrow, slightly convex on one of its sides, and the back of which was blunt up to near its point. To these he added a cystotome, a sort of triangular lance, supported by a padded spring, (*ressort en boudin*.) and enclosed in a sheath which was dilated in its middle in such manner as to resemble the body of a syringe. *Beranger* soon after modified the keratotomy of *La Faye*, gave it more breadth, rendered it flat on one side, convex on the other, and much thicker, especially on its back. *Sigerist* gave still greater length to the point of *Pallucci's* knife, in order to open into the capsule by traversing through the anterior chamber. But *Jung* has remarked, with great propriety, that a cataract needle is much better than any particular kind of cystotome for this last stage of the operation. It was during this state of things that *Richter*, who appeared in Germany, *Wenzel* in France, and *Ware* in England, definitively established the rules for the method by extraction. Two methods have been proposed for extracting cataract. One, but little known in France, bears the name of *scleroticotomy*; the other, almost the only one in use, is called *kératotomy*. The same *preparatory steps* are applicable to them. The pieces of dressing are similar to those which are required for depression. Nevertheless the position of the patient, assistants and operator, require still more exact precautions than in this last method.

It is for extraction especially that *Richter* and *Beer* urge the necessity of a chair with a solid and vertical back, against which they assert it will always be more easy to keep the head of the patient immovable, than by supporting it against the chest of an assistant. The horizontal position proposed by some, and extolled by *Rowley* and *Pamard*, is nevertheless but rarely adopted; doubtless, because it is a little inconvenient for the surgeon. I have often made use of

it, and do so daily, and I confess I never have been able to comprehend why it is not more frequently had recourse to. In that case, it is necessary for the surgeon to place himself upon the side of the eye affected. Should it not, however, be adopted, and that it should be thought preferable to place the patient on a chair, it is, if not indispensable, at least more convenient for the surgeon to stand up than to be seated before him. The speculum devised by F. Aquapendente, still employed by Sharp, and modified by Heister, the instrument of Van Wy (Arrachard, *Dissert.*, &c., p. 69, 106, Paris, 1805,) the ring of Bell or Assalini, which M. Lusardi has placed upon a handle and reproduced under a new form; the erignes of Sommer, and all the other instruments invented to separate apart, elevate or depress the eyelids, which are useful when we have not a sufficient number of expert assistants, are advantageously replaced by the fingers. Almost all of them incur the risk of compressing or of emptying the eye. The same remark may be made of *ophthalmostats*, among which are to be mentioned the forceps of Ten-haaf, the pique, the stem of which Casamata caused to be curved into an S, in order that it might be better accommodated to the form of the nose, which Rumpelt attached to a sewing thimble, in order to use the middle finger while the forefinger of the same hand depresses the lower eyelid, and to which Demours wished to add another modification by mounting it upon a thimble open at its two ends. The trefoil (*trèfle*) of Pamard, such as the son-in-law of the inventor made known in 1825, is liable to nearly the same objections. I find it less dangerous, however, than to apply the two first fingers of the assistant and the operator in the great angle, as is recommended by Ware, to prevent the eye from inclining inwards, and to compress it up to the moment at which the knife terminates the flap of the cornea. The species of elevator, the kystotome forceps, the double keratotomy of M. Martin, the instrument contrived by M. Bonnefin (*Thèse*, No. 41, Paris, 1837), are doubtless constructed with sufficient ingenuity, but may be too easily dispensed with to make their utility a matter of importance with surgeons. The ophthalmostat of M. Fardeau (*Journ. Hebd.*, 1835, t. IV., p. 117,) differs from that of M. Lusardi in this, that in place of a prominent arc, it carries on its ring a kind of large concave and blunt nail (*ongle*). That which I have proposed, (Estevenet, *Journ. Hebd.*, 1836, t. II., p. 147,) has some analogy with the ancient probe of Segwart; resembling in its handle the ordinary keratotomy, it is composed of a small plate of shell, slightly curved on its flat side, and which, moreover, represents the scoop of Daviel. Being perfectly blunt and destitute of any kind of roughness, this plate irritates the parts in no respect whatever. As soon as the point of the knife has passed through the cornea at the side of the great angle I glide this instrument below and between it and the sclerotica, in such manner, that by holding the eye immovable in that position, I render it impossible for it to become displaced inwards, giving at the same time a point d'appui to the keratotomy, which allows me every liberty desirable for completing the section of the cornea.

I. *Scleroticotomy*.—B. Bell, after making some trials upon the dead body, averred that it was full as easy to extract the cataract by the

sclerotica as through the cornea. This idea, the first application of which upon living man was made by Earle, and which was revived by D. Lebel and M. Giorgi, has been definitively adopted by M. Quadri, of Naples, who founds upon it his new method or that of scleroticotomy. An incision of about three lines in length is first made by any keratome whatever, upon the sclerotica at two lines from the cornea. The crystalline and its envelope are then seized hold of by means of a small pair of forceps, and the whole extracted through the outer angle of the eye. In proceeding in this manner, M. Quadri affirms that he failed but in four instances out of twenty-five operations. The first stage of the operation is less difficult, and exposes perhaps to fewer immediate accidents than the ordinary method, nor can it be very difficult to seize hold of the cataract; but how can it be embraced with sufficient firmness to enable us to bring it through the opening of the sclerotica without emptying the eye? How can it be believed that so large an incision through the three principal coats of the eye, will not, in a majority of instances, be accompanied by an internal hemorrhage, wounds of the ciliary nerves or vessels, and followed by accidents a hundred times more serious than those which take place after the opening through the transparent cornea?

II. *Keratotomy*.—Extraction, properly so called, is composed of three different stages: the incision of the cornea, the opening into the capsule, and the expulsion or extraction of the crystalline through the incision whether made upon the inferior or superior half of the eye. The *instruments* employed to effect this have varied considerably, and are far from being the same with all operators. In France, they freely employ the knife of Wenzel, the inventor of which, Richter, (*Bibl. Chir. du Nord*, p. 212,) has so severely censured, and which differs from that of La Faye only in this, that neither of its sides is more convex than that of the other. Some practitioners however prefer the keratome of Richter, the blade of which, which is very pointed, expands from the point towards the handle in such a manner that it may divide one half of the segment (limbe) of the cornea while traversing the anterior chamber. That of A. Pamard resembles half a myrtle leaf, and has, upon its upper border, which is straight and blunt, a small rib, in order to increase its force. Ware's knife, which is generally employed in England, is almost in every respect similar to that of Richter, and the instrument of Beer, so much praised in Germany, differs from it only by the shortness of its point, and in having a little less degree of length in its blade, which latter, moreover, is somewhat broader. Béranger has proposed one which is convex on one side, flat on the other, and somewhat broader than that of La Faye. Lobeinstein gives it still greater breadth, and slightly elongates its point. Under this form, its convex side, turned backwards, protects the iris, while its plain surface glides behind the cornea. This knife, slightly modified by B. Bell, has since been improved by Jung, one of the most skillful cotemporaries of Beer. According to Sprengel, the keratome of Jung, which is convex on both sides, and cutting on both its edges, is very short and somewhat broader than is necessary to divide with one stroke half the circle of the cornea. According to M. Harel, on

the contrary, the knife should be like that of Lobstein, convex only on its posterior side, and should resemble a kind of guillotine. Finally, that of Barth is distinguished from the preceding by the small notch which is found near its back on one of its sides. The important point in the midst of so great a number, is to choose an instrument whose form and dimensions will enable us to divide completely the half of the cornea, in traversing the anterior chamber, without giving egress to the aqueous humor while the knife remains in the wound. To effect this object, its blade, being of a triangular form, ten lines in length, at least three lines in breadth near its heel, and slightly convex on both its sides, ought to be somewhat thicker at its back than near its cutting edge, and should gradually increase in thickness from the point to the handle. In this respect, Richter's knife, somewhat shortened as Beer has recommended, appears to me to deserve the preference over all the others. I have had constructed a carp's tongue, four lines broad at its heel, six lines long, terminated by a point somewhat tapered, and which is more convenient for laying open the cornea than the lance of Daviel. An instrument which is longer, of less breadth, and with a point more projecting, has been proposed by M. Furnari for the same object. It is however perfectly understood that we may, if necessary, make use of a simple lancet, the little sickle-shaped knife of Sharp, a very sharp-pointed bistoury, or, in fact, any cutting instrument whatever. The point under these circumstances is, which is the best, and not what is of absolute necessity.

The *second stage* has also attracted much attention from surgeons. The needle of Thuraud, the lancet of Tenon, those of Hellmann and Grandjean, Mursinna's probe, and the kystotome of La Faye himself, with or without the modification of M. Rey or M. Bancal, are generally abandoned. The serpette of Boyer would have also fallen into disuse, if the scoop of Daviel, which Dusaussay (*Gaz. Salut.* 1786, No. 29, p. 3,) considers that he has improved, and which is still sometimes made use of, was not mounted upon the same handle. Small and straight forceps, having a small hook at their extremity, like those of Reisenger; the erigne forceps of Blaemer, or the tooth forceps of Beer; in fine, an ocular forceps, such as are found at every cutler's; a hook-needle; a small spatula or gold scoop, and Anel's syringe in case of necessity, and which are useful, either for detaching or afterwards removing any fragments of capsule, of membrane or of crystalline; ought also to be placed by the side of the knife on the operating table. In a woman on whom I operated for a *black cataract* at the Hospital of La Pitié, the capsule was so thick and so firm, that it resembled in almost every respect the cornea, causing me a vast deal of trouble to open into and to extract it, for which cases the instruments could not be too sharp. An ossified crystalline, as in the case cited by M. Middlemore, (*Transactions of the Prov. Assoc.*, vol. VI.; *Revue. Méd.* 1838, t. III., p. 269,) would not be more difficult of expulsion than any other. It is probable, however, that if the cornea or vitreous humor were indurated, as in the patients of M. Wardrop and Kulm, the operation for cataract would hardly be thought proper.

*a. Inferior Keratotomy.*—1. *Ordinary Process.*—*First Stage.*—

The patient and the assistants being properly arranged, the surgeon depresses the lower lid with the forefinger, which he at the same time presses against the caruncula lachrymalis, in order to support the globe of the eye on the inside; seizes the cataract knife with the other hand; directs its point at a line or half a line in front of the sclerotica, while taking with his little finger a point d'appui on the temple; then plunges the instrument immediately into the anterior chamber perpendicularly to the axis of the cornea, a little above its transverse diameter, and at the side of the outer angle of the eye; immediately inclines backwards the handle of the knife, whose point without this precaution would not fail to wound the iris; then pushes it horizontally with firmness, and without any shaking, to a point diametrically opposite of the cornea, which he again pierces, but from the interior to the exterior; makes it advance upon this line without pressing upon its cutting edge; takes care never to withdraw it towards the outside, and that one of its sides should be exactly parallel to the anterior surface of the iris, while the other looks towards the front part of the eye, until in the progress of its track it has entirely divided the inferior semicircle of the cornea, as near as possible to the sclerotica, that is to say, at a line or half a line from the greater circumference of the iris. It is at the moment when the keratotome terminates this section, that the slightest pressure would be particularly dangerous, and which it is important therefore to avoid, as far as it is in our power to do so. At the same instant, therefore, the assistant is to let go his hold upon the eyelid, which the patient, to whom some few moments are accorded to recover himself from his emotion, gently closes.

*Second stage.*—After having carefully wiped out the vicinity of the orbit, the surgeon raises up the eyelid or causes it to be raised a second time, taking particular care not to touch the globe of the eye; presents with the other hand the back of the kystotome at the most depending point of the wound; penetrates in this manner to above the pupil, whose superior semicircle he passes around by preference from one side to the other, and in such manner as freely to divide the crystalline envelope with the point of the instrument whose concavity is to be turned downwards. When the two eyes are to be operated upon successively, the surgeon rests here for the first, in order not to return to it, until after having opened the cornea and capsule of the second.

*Third stage.*—If the cataract does not of itself pass into the anterior chamber, its expulsion is to be favored by means of gentle pressure properly applied. The operator pushes the left forefinger against the lower part of the eye. With his right hand he places the handle of the keratotome or the back of Daviel's scoop, transversely, upon the upper eyelid, in order to execute while making pressure, slight movements backwards and forwards, upon a level with the ciliary circle, in the direction of a line which would reach from this point to the union of the two anterior thirds with the postero-inferior third of the sclerotica, in passing from above downwards between the crystalline and the vitreous humor. Immediately the lens is seen to pass through the pupil, and to present itself by its border, at the wound of the cornea, which it escapes from, or from which we force it to escape

by gradually directing upon it the pressure from above. We then remove it with the scoop, needle, or point of the knife, when the operation is usually found to be terminated.

*Fourth stage.*—If opaque fragments of the capsule, of such large size as to compromise the success of the operation, should be found to be left behind, they are to be seized hold of and extracted with the forceps. Any other fragment should be removed in the same manner, should the spatula or the scoop prove insufficient. As to those which become arrested in the anterior chamber, unless they should be of a certain volume, it would be much better to abandon them to the dissolving action of the humors, than to irritate by repeated trials with Daviel's scoop, the posterior surface of the cornea. The same remark may be applied to the disfluent layer which is sufficiently often detached from the crystalline, when it escapes into the anterior chamber, and remains adherent to the environs of the wound. Whether the contact of the instrument with the membrane of the aqueous humor inflames this lamella, as Sommer has asserted, or whether it is detrimental in any other way, certain it is, that a manœuvre of this kind is frequently followed by a complete and speedy opacity of the cornea. Warm water injected into the chambers of the eye with Anel's syringe, as Forlenze was in the habit of doing, would evidently be much preferable. As to the dangers of air, which according to M. Maunoir, (Carron du Villards, *Oper. de la Catar.*, p. 156, 216,) gets into the eye in place of the crystalline, making it necessary to fill the anterior chamber with distilled water to drive out this gas, I must differ in opinion from the skilful surgeon of Geneva.

2. *Remarks.*—In place of commencing the *incision* exactly at the extremity, or a little above the *transverse* diameter of the eye, *Wenzel* recommends that the knife should be directed upon the middle of the outer and upper fourth of the cornea, and that it should be made to come out at the same point on its lower and inner fourth. His reason is, that by this mode the root of the nose runs less risk of being wounded, and that the wound being oblique, the eyelids forced in closing to conceal its two extremities, cannot either of them become entangled between its edges. This precept, which is generally recognized in France, is far from having attracted as much attention in other countries. In Germany, for example, it is so little known, that *Weller*, who advises it, appears desirous of appropriating the mode to himself. We should be wrong, perhaps, not to adopt it when the eye is large and projecting, because under such circumstances, the lower palpebral border in fact might have a continual tendency to open the lips of the wound; but in other cases, the advantages which are attributed to it, certainly originate much more from theoretical ideas than from practical facts. The puncture of the inner angle of the eye is a matter of too little consequence to be regarded, and the natural pressure made by the upper eyelid usually suffices to prevent the separation of the edges of the wound, whether it be transverse or oblique. Then again, the projection which usually exists in most persons in the outer orbital process, and that of the superior maxillary bone near the ascending process, cannot but have the effect to impede the march of the instrument, and of in-

curing the risk of making such tractions upon the eye, as to endanger the expulsion of the vitreous humor. Between the two angles of the eye, nothing similar is encountered. When judged necessary, it is generally under such circumstances practicable even to incline the handle of the keratotome towards the temple beyond the transverse axis, without making severe tractions on the eye. In incising at less than half a line from the cornea, it would be with difficulty that we could avoid the iris; at more than a line we should have to apprehend that after the cure, the opacity of the cicatrix would be brought too near the centre of the pupil. A stage which students have most difficulty in comprehending or executing properly, is that which consists in falling perpendicularly on the eye. It is, however, a point of the highest degree of importance. If we approach more to the horizontal line, the point of the instrument, almost always becoming entangled between the laminae of the cornea, works itself obliquely through them, and sometimes does not reach into the anterior chamber. but at a line and a half from its entrance, making in reality but a small aperture, though in appearance the wound is very large.

To attain the object desired, the surgeon must not lose sight of the position of the eye, and that according as this organ is more or less turned inwards, he must always present the instrument to it from before backwards, and from without inwards, but more or less inclined towards the temple or towards the face. We should also at the same time recollect that the cornea being curved upon a cord shorter than the sclerotica, there must exist in front of the union of these two membranes a slight circular excavation, which causes its perpendicular to be a little less inclined forwards as compared with the diameters of the body of the individual, and the perforation more easy. As soon as the *knife has entered into the anterior chamber*, its cutting edge must be kept downwards as accurately as possible, in order to avoid the ciliary circle and iris behind, or having a cicatrix too near the centre, should it be inclined forward. At the moment when its point is about to emerge at the side of the caruncula lachrymalis, it would, should it not be directed a little towards the anterior plane, bear too much upon the sclerotica, and might again wound the cornea. As soon as we have commenced inserting it, it is important not to give it any retrograde movement until it has completely traversed the eye. The gradual increase of its thickness and breadth, enables it to fill up the wound exactly, from whence it follows that the aqueous humor does not flow out till at the end. However little it may be withdrawn, on the contrary, it leaves necessarily a void from whence this liquid immediately escapes. The iris then protrudes forward, and may be easily wounded. The rule is, that we should detach the half of the circle of the cornea. A smaller wound would render the expulsion of the crystalline difficult, especially should it be of a large size, and would necessitate dangerous pressure. Should the wound be greater, there could be but little inconvenience in it. Were extended it to two-thirds of the cornea; but though in such cases gangrene of the flap, dreaded by Maunoir, can scarcely be apprehended, it is nevertheless unnecessary to go so far. Should it be necessary to enlarge the incision of the cornea, the

instrument in form of a double lithotome, devised by M. Carron du Villards, (Marini, *Bull. de Therap.*, t. VI., p. 282.) might be serviceable, and would readily enable us to attain our object. When the *eye obstinately continues at the vault of the orbit*, the trefoil of Parnard may be required to render the process of extraction practicable; if it is concealed at the great angle of the eye, we may sometimes bring it out by means of the finger directed upon the caruncula lachrymalis; and better still, with the scoop (*curette d'ecaille*) which I am generally in the habit of using. It could be fixed without difficulty and even without danger, between the middle and forefinger of the assistant and the operator, if we could feel perfectly sure that we could suspend all kind of pressure the moment the knife had penetrated through and through the cornea, that is, a little before the definitive formation of the flap. At least I do not see any risk in proceeding in this manner, until the point of the knife arrives in the great angle. Then we are masters of the organ, and no obstacle prevents our bringing it forward, provided, however, the blade of the instrument is not displaced. In place of the *sound* or flexible probe, which were used by Pellier and Siegerist, we might, when the pulp of the finger did not appear to be capable of effecting our object, use advantageously the nail of the *forefinger*, or even of the little finger, to aid the knife in terminating the flap of the cornea. The extremity of the finger is then directed upon the great angle, in such manner that its pulp falls perpendicularly upon the inner side of the eye, at the same time that its back faces forwards and towards the median line. As soon as the keratome presents itself, its cutting edge is placed at a right angle on the free border of the nail, as if to support it; after which, while making it pass from the external to the internal angle of the eye, the nail fixes the cornea by making a slight effort, as if for the purpose of gliding outwardly towards the heel of the instrument, until the incision is completed. The shell scoop which I am now in the habit of employing, substituted in place of the nail, renders this stage of the operation still more simple and easy.

In spite of all these precautions the *iris* will sometimes *present itself* under the cutting edge of the knife. Gentle frictions on the front part of the eye, through the upper lid, often oblige it to withdraw itself backwards, either because we in this manner favor its contractions and its narrowing, or, as appears to me more probable, because the pressure that we must almost necessarily make upon the cornea, restores it to its natural position, by forcing the liquid which is in front of the keratome from the anterior into the posterior chamber, or perhaps because we straighten its folds by flattening the vitreous membrane. Certain it is that we never succeed better than when we apply the finger naked upon the eyelid, and moderately compress it. After all, the worst that can result from it is a second pupil; which accident has happened to Wenzel, M. Roux, and Forlenze; numerous examples of it are to be found in the works of authors. It has happened many times with myself, and I have not found that the re-establishment of the sight has been thereby interfered with. I am therefore of opinion that it is less dangerous to incur the risk of this accident, than to withdraw the knife to finish the incision with

the scissors, and that prudence, moreover, allows us to dispense with it, if in order to avoid it we expose the eye to fatiguing manipulations. *The elasticity of the sclerotica*, and perhaps also the action of the recti muscles, may quite frequently be found sufficient to expel the crystalline, which then immediately presents itself at the wound, as soon as the instrument is withdrawn, or a short time after. It is indeed owing to this fact that many practitioners have suggested the idea of opening the capsule at first, and not to return to the expulsion of the cataract until after having proceeded in the operation to the same extent upon the other eye. Bell, and after him Jung, from fear of breaking up the crystalline, have proposed to *scrape the capsule* rather than incise it. After having cut through the cornea, M. Jüngken (*Jour. de Kleinert*, Juin, 1836, p. 76,) considers that the chances of success would be augmented by removing the capsule before extracting the crystalline. It is a practice which is decidedly pernicious, and which nothing but the extreme skill of the German oculist has rendered somewhat popular. Pellier, Siegerist, and especially Wenzel, have considered that it would be better to *open this membrane with the keratotomy while passing through the anterior chamber*, than to return to it afterwards. It was an easy thing for Wenzel, who reached its anterior layer by inclining slightly backward the point of his knife, when it was passing in front of the pupil. For operators who are less experienced, it would be an exhibition of force, and an act of imprudence which might be attended with danger. The operation would be uselessly complicated by raising the flap of the cornea with a spatula, while another instrument was being directed towards the pupil. The cataract knife is rarely employed for this incision, because the iris might thereby be easily wounded. Hey's needle, the little myrtle-leaf of Morenheim, and the spear-shaped instrument of Beer, are special instruments which are replaced by the ordinary curved needle, or the serpette of Boyer, which, however, in consequence of its convex and rounded border, is much better adapted for going through the wound than lacerating the crystalline envelope. I would say the same of the instruments of M. Furnari, which, nevertheless, are constructed with considerable ingenuity. This surgeon after having incised the cornea with his lance-shaped knife, the point of which at the same time lays open the capsule, proceeds to break up the crystalline in its place, by means of a kind of small polypus forceps, which afterwards allows of expelling or extracting it without difficulty through the incision. *The crystalline escapes* readily through a puncture in the centre, or a semilunar incision at the depending point of the capsule, as well as by the numerous incisions vertical and transverse, which Beer was in the habit of making upon it, because it lacerates what makes resistance to it; but the flaps of the opening afterwards approximate, or fall back again into the visual axis, and may, should they become opaque, produce a secondary cataract. On the contrary, by placing the semilunar incision above, as I have recommended, the tearing open of the capsule is made from above downwards, in such manner that the flap which results from it must remain below the pupil. Beer, perceiving that it was sometimes exceedingly difficult to effect this destruction of the capsule conveniently,

decided upon removing it entire, either by means of a hook in cases of silicose cataracts, or by a small forceps, when it is an encysted cataract, or finally, in cases of capsulo-lenticular cataract, by means of his needle-shaped lancet. Richter, maintaining the idea, that, in depression, the capsule and crystalline are always reversed together, (*Bibl. Chir. du Nord*, pp. 269, 271,) asserts that in the operation for extraction also, it is advisable and not difficult to remove them both at the same time. Though Beer asserts that he has often followed this precept with success, he has not found, and will not find in the future but a very small number of partisans. Who, in fact, does not see that the remedy is worse than the evil; that we should succeed much better by making free incisions into the capsule than by detaching it in mass; that by these repeated movements the crystalline will, in most cases, lacerate it, and leave it remaining, so much the more so as the posterior capsular layer is not susceptible of being readily detached from the vitreous humor. It is not often, moreover, that this deep-seated portion of the crystalline envelope becomes opaque. This is fortunate, for unless it was very limited, the evil probably would be without a remedy. Even in such cases I do not know to what extent it would be allowable to follow the advice of Morenheim and Beer, by isolating the opaque point, and attempting its extraction with a hook. I do not think that the laceration of the posterior capsule in many directions, after having extracted the crystalline, as is recommended by M. Landrau, (*Arch. Gén. de Méd.*, t. XIV., p. 113,) would be a prudent course, or present the slightest advantage.

It has been suggested when the cataract was milky to give egress to the altered liquid, or when it was membranous to destroy the capsule only, in order to preserve, according to M. Jüngken, the crystalline in its place with its natural transparency; as if in liquid cataract the whole lenticular apparatus was not at the same time diseased; as if the crystalline could maintain itself with its normal conditions a moment after the capsule had been opened! Diseased or not, it should be removed in every case therefore, should there be no obstacle to our doing so. The *putrid* cataract of Schifferli does in reality exist; an instance of which I saw at La Charité in 1837. The lenticular capsule, which was of a greyish color and very much distended, extended beyond the plane of the pupil in front. The purulent matter which it contained, emitted in coming out an infected odor which surprised all the assistants. In producing a dilatation of the pupil the preparations of belladonna, which were already in use in such cases in the time of Pliny (Carron du Villards, t. II.) and Raymar (Causard, *Thèses de Paris*, &c.) give greater facility to the egress of the vitreous humor, and may in this manner become more or less dangerous. If they are omitted the pupil sometimes remains so contracted as to interfere with the expulsion of the crystalline. In order to obviate these two inconveniences, Bischoff and others have recommended that we should first open the cornea, then the capsule, and afterwards turn the back of the patient to the light when we desire to expel the cataract. By this means the pupil, which was strongly contracted in the beginning of the operation, becomes, they say, dilated of itself, and without any danger towards

the termination. If it were necessary, we might also, say these same practitioners, not make use of any medicated applications until after the eye had been opened into; as if the pupil could then respond to the action of belladonna!

Finally, before proceeding to any active means, we must cause the globe of the eye to be moved upwards, inwards, and outwards, seeing that such movements frequently favor the egress of the opaque body. If from some cause or another the vitreous humor escapes, we must immediately close the eyelids and turn the head of the patient towards his back. This accident, which involves the complete loss of the eye when the hyaloid membrane is entirely emptied, is in the other cases much less dangerous than has been for a long time supposed. It has in fact this thing remarkable about it, that the loss of a certain quantity of the vitreous humor seems rather calculated to augment than to diminish the prospect of a favorable result for the operation. The loss of a fourth part or even a half of this liquid ought not to cause us to despair of success. There is no evidence that it is again produced; but the aqueous humor being more abundantly secreted, takes its place, and the functions of the eye scarcely suffer.

3. *Process of Guérin and Dumont.*—With the view of reducing the operation to its most simple condition, Guérin, and almost at the same time, Dumont, captain of the coast guard in Normandy, each contrived an instrument, the object of which was, by an ingenious mechanism to hold the eyelids apart, steady the globe of the eye, and complete the incision of the cornea by one stroke. The first of these instruments, terminated by a sort of ring bent to a right angle on its handle, concave behind, and shaped to the front of the eye to which it was accurately adapted, includes a cutting blade in form of a fleam, which being put into operation by means of a spring, immediately divides the half of the circle of the cornea either from below upwards or from above downwards. The ring and the handle of the second are upon the same line. Its blade has some analogy to the pharyngotome, and is to be applied horizontally, differing in this respect from the other, which falls on the eye in the manner of the cutting edge of a guillotine. The instrument of Guérin, which was suggested perhaps by the fleam of Van Wy, has been long since abandoned in France, and M. Eckhold, after having modified it, is the only person to my knowledge who has been desirous of its adoption in Germany. Though more convenient and less dangerous, that of Dumont has not met with a better reception.

4. *Guérin of Lyons*, (*Mal. des Yeux*, p. 380, 1769,) uniting the lance of Pamard with the keratotome, was not more fortunate than his namesake of Bordeaux.

If the instruments of which the ancients were so lavish, if every species of brute force has been so carefully rejected from practice in the operations of modern surgeons, with still greater reason ought they to be proscribed on the eye, which is an organ of such delicacy and so easily destroyed. The stroke which is necessarily given to them by letting loose a mechanical spring, the danger of wounding what it is important to avoid, of making an opening either too great or too small, and of cutting sometimes too near and sometimes too far from the sclerotica, are the reasons which have especially intimi-

dated practitioners. It would, however, be unjust to accord no praise to such inventions, and to qualify them as absurd, as some have done, without having it in our power to judge of them with a full knowledge of circumstances. A number of physicians can attest, like M. Hedelhofer, that Petit of Lyons frequently and successfully made trial of the instrument of Dumont. Modified by the nephew of its inventor, it has been said to have obtained sixty-two successful results out of seventy-one operations, if we can receive literally all that has been said of it. What we may affirm is this, that notwithstanding the improvements which have been made upon it by M. Guépin, (*Soc. Méd. de Nantes*, 1834, 2d trim., p. 46,) the instrument of Guérin has been completely proscribed from general practice.

*b. Superior Keratotomy.*—When the lower semicircle of the cornea is opaque or altered in any manner whatever, its section is, in the first place, quite difficult in certain cases. Afterwards the wound is found in unfavorable conditions for cicatrization. This membrane, though sound, may be very small, so that it becomes necessary to detach more than half of it in order to obtain a sufficient opening. In such cases Wenzel advises that we should divide the superior semicircle, and states that he found it to answer perfectly well in the case of the Duke of Belford. Richter is of the same opinion, and B. Bell has formally advised it, even for ordinary cases. According to him there is less danger of the escape of the vitreous body, the cicatrix of the cornea is perfected more rapidly and is less perceptible, and less troublesome to the vision than by the ordinary process. M. Wagner states that M. Alexandre has not hesitated to put the suggestion of Wenzel to a trial, and M. Wilmot, as quoted by M. Eccard, asserts that MM. Lawrence, Green, and Tyrrel have frequently employed it. Dupuytren, in France, also thought proper to make trial of it: but nobody, before the time of M. Jaeger, had gathered a sufficient number of facts upon living man to establish it into a general method. With the upper incision, says M. Jaeger, we have nothing to apprehend from the friction of the palpebral border or of the eyelashes, the tears run more freely and irritate the wound less, which, in its turn, does not so often suppurate, while the prolapsus of the iris must be very rare. A difficulty which first arrested his attention, was the tendency of the eye to turn inwards, or to reverse itself under the upper lid. In this respect he believes that he has removed every objection, by contriving a peculiar keratotome formed of two blades, one of which is a little less than the other, applied face to face in such manner as to represent the knife of Beer or Richter when it is closed. By pressing upon a lateral button the small blade is made to glide upon the large one as in opening a knife with a sheath. The patient and the assistants are to be arranged as in the ordinary method. The operator seizes the double keratotome in the manner of a writing-pen, turns its cutting edge upwards, and passes through the anterior chamber parallel to its transverse axis, while conforming himself in other respects to the precepts laid down above. This being finished he brings back the globe of the eye to its natural position, even depresses it a little if necessary, and fixes it by means of the largest blade of the knife, while the other blade put into operation by the thumb of the same hand, effects the division of the cornea in

gliding from its point to its base. M. Alexandre, (Wagner, *Bull. de Féruss.*, t. X., p. 284,) who, after having passed through the cornea, leaves a bridle of it which he afterwards divides with a small blunt-pointed knife, appears to have acquired such practice in the use of this instrument, that he can operate alone and without assistants. Since M. Jaeger, in the space of six months, has forty times extracted cataract successfully by means of his double keratotomy, it would be incorrect to say that this instrument was positively objectionable. *A priori*, nevertheless, it is difficult to understand its advantages. If it be true that we may firmly fix the eye with its immovable blade, while its other blade is dividing the upper segment of the cornea, it must, on the other hand, pass through the tissues with greater difficulty. Upper keratotomy, moreover, may be very well performed with the ordinary knife. M. Graefe, (*Arch. Gén. de Méd.*, t. XXI., p. 271,) who has used this successfully in seventeen out of eighteen cases, among others upon the Duke of Cumberland, believes it preferable to the double keratotomy, and I have employed no other instrument in the fifteen cases in which I have had recourse to this kind of keratotomy. As to the operation in itself, of all the advantages that are ascribed to it, there are very few that are substantial. It perhaps exposes less to a wound of the iris, to the escape of the vitreous body, and to the separation of the wound by the border of the eyelids; but the manipulation in all its stages is unquestionably more difficult and less secure than in lower keratotomy. How can we afterwards proceed to laying open the capsule, if the eye keeps itself raised up under the vault of the orbit? What means have we of depressing it, if the will of the patient does not effect it? How direct the pressure, if the crystalline delays in coming out? And the attending circumstances of cataract, can it be supposed that it will be always in our power to reach them? It is, therefore, a method of exception and not of choice, applicable only to the cases pointed out by Wenzel, even supposing then that it would not be preferable to recur to the employment of the needle.

III. *Dressing and subsequent treatment.*—Dressing and the subsequent treatment after extraction differ but very little from what has been recommended after depression, only perhaps that it would not be altogether useless, before covering his eyes, to exhibit to the patient some objects that are not shining, to see if he distinguishes them. It is not in order to gratify mere motives of curiosity that this precaution is recommended, but because we are obliged by such a test, when it is not satisfactory, to ascertain again if some opaque substance which it is important to extract, does not remain in the eye. Repose, avoidance of all movements of the eye and the upper portion of the trunk, now become of more absolute necessity than ever. Though the head should be only slightly elevated, I see no reason, however, which should induce us to place it lower than the feet, as was done by Forlenze. The regimen ought to be more rigid, and continued for a longer time, a longer interval also allowed to elapse before the first dressing, and the eye not so soon exposed to the light as after depression.

*The suppuration of the cornea*, (la fonte de la cornée,) which we have especially to dread, ought to be watched with extreme atten-

tion. We can prevent or arrest it only by means of very energetic treatment; bleeding to the amount of from twelve to sixteen ounces morning and evening, leeches to the temples, purgatives internally, and cutaneous revulsives, simultaneously employed the first, second and third day, are not too severe in such cases. It is important even that we should not hesitate, but recur to it immediately as soon as the linen which covers the eye becomes soiled, and as it were saturated with pus, and that the patient complains at the same time of pains in the orbit, before the fourth or fifth day after the operation.

E. *Comparative examination of the processes.*—I. *Depression*, which was alone in use up to the middle of the last century, fell into such discredit, in France at least, after the publication of the labors of Daviel, that in spite of the efforts of Pott to cause its revival, it was scarcely any longer had recourse to by any one at the commencement of the present century. The modifications which it has received from Scarpa rescued it from this oblivion. But the question, which of the two methods is the best? which has so often been debated, and always remained undecided, is still daily revived. In admitting that it is not incapable of solution, it must nevertheless be conceded that the circumstances which enter into its nature are difficult to be appreciated. How can we conclude, for example, because one process possesses a greater number of distinguished partisans than another? because Scarpa, Hey, Dubois, Dupuytren, Richerand, Béclard, Lusardi and Langenbeck, have procured a greater proportion of cures by depression than by extraction; while for Wenzel, Richter, Beer, Demours, Boyer, Roux, Forlenze and Pamard, the case is precisely the reverse? As soon as an operator has made choice of a method which he is in the habit of employing, his predilection always more or less deceives him, and renders him, in most cases, unfit to judge of other methods. Nor are the results, announced by different men equally well instructed, decisive arguments. The successful issues procured by Dupuytren from depression, in no wise prove that this operator would have been less fortunate, if in the beginning he had exerted himself to give popularity to extraction. In promulgating that by means of extraction Sharp had the same number of successes as reverses; that Richter succeeded in 7 times out of 10, Pelletan and Dupuytren 20 out of 50, M. J. Cloquet 28 out of 80, M. Roux 188 out of 306, and A. Pamard 302 out of 359, we prove nothing more, either for or against this method, than do we demonstrate the pre-eminence or inferiority of depression, by saying that in this manner Beer, Weller and M. Roux have failed in more than half their cases, while Dupuytren cites five cures out of six cases, M. J. Cloquet 97 out of 166, M. Bowen 154 out of 160, and M. Lusardi 4168 out of 5034. M. Robertson, (*Presse Méd.*, t. I., p. 430,) having examined 1307 cases of operation by extraction, taken from twelve different authors, has ascertained that 397 of them were failures, while out of 7529 examples of depression, there were but 104 failures. Out of 64 patients that he himself operated upon by extraction, he cured 32; 14 obtained some relief from the operation, while 18 remained uncured. In 115 cases of depression, on the contrary, he procured 94 cures, with 10 cases of amelioration, against

11 failures. M. Serre, (*Bull. de l'Acad.*, t. I., p. 90,) who adopts depression, states that he has succeeded in 62 instances out of 70.

In the table of Brunner (*Anc. Journ. de Méd.*, t. 84, p. 80, and especially p. 86, 1790,) we find 252 extractions, and out of them 149 favorable, 24 mediocre, 61 unfavorable; out of 169 depressions, 134 favorable, 36 unfavorable; out of 100 extractions, 59 favorable, 17 mediocre, and 24 failures; out of 100 depressions, 79 favorable and 21 failures. M. Fabini, (*Bull. de Fér.*, t. XXVII., p. 71,) who in 107 patients, operated 100 times by extraction, states that he obtained 71 cures. In an aggregate of 179 cases of extraction by M. Roux, (Maunoir, *Thèse citée*, p. 78, 79,) there were at one epoch 97 cures and 89 failures. Suppose, in order to show how deceptive this kind of proof is, that the twenty most skilful surgeons of Europe have operated only by extraction, while 20 others taken at random, have always had recourse to depression. Because the practice of the first shall have furnished a larger proportion of cures than that of the second, does it necessarily follow and by that proof alone, that extraction is preferable to depression?

II. Let us see whether, after having passed in review the principal advantages and inconveniences of both methods, we may not arrive at something more satisfactory.

*Extraction* enables us to remove with certainty and without a return of the disease, the impediment to vision. Besides being attended with but little pain and rarely followed by an internal inflammation, it incurs the risk of wounding neither the ciliary nerves or vessels, leaves intact the whole interior of the eye, the retina, choroid, ciliary circle, &c., but in performing it, we may wound and deform the pupil, and cause the escape of vitreous humor; if the wound which it produces does not cicatrize by first intention, it ulcerates, soon brings about a prolapsus of the iris, and sometimes an atrophy of the globe of the eye, or at least a very extensive opacity of the cornea; the subsequent symptoms also are tedious; it rarely happens that the ophthalmia which accompanies it, terminates before the fifteenth or twentieth day; finally, it cannot be employed in all persons nor at all ages. M. Roux, (Maunoir, *Thèse citée*, p. 81,) who operated upon 43 cases in the spring of 1833, had the misfortune to lose three of them. In 35 patients operated upon in 1836, by the same practitioner, (*France Méd.*, t. I., p. 50,) the escape of the vitreous humor took place in five; the iris was wounded several times; and a violent inflammation of the eye occurred in eleven cases. Thirteen patients recovered their vision perfectly. The result was incomplete in eight others; in fourteen cases the operation did not succeed. One of the patients operated upon, died of erysipelas. In 179 patients operated upon by M. Roux at another epoch, (Maunoir, *Thèse citée*, p. 79, 80,) suppuration of the eye took place in 14 cases, opacity of the cornea in 28, and a false cataract occurred in 22. It would appear, however, according to M. Maunoir, (*Thèse citée*, p. 49,) that at La Charité, during the time of M. Roux, membranous cataract was ascertained to have occurred but in 5 instance out of the above mentioned 179 cases.

*Depression* confines itself to displacing the opaque body, and abandons it in the depth of the organ, leaves there, consequently, a

permanent cause of irritation in the eye, incurs the risk of the reascension of the crystalline, and is frequently followed by secondary membranous cataract, iritis, deep-seated pains and general nervous symptoms. The needle penetrates through delicate tissues, necessarily wounds the choroid, the retina and the vitreous humor, and sometimes also the iris and ciliary body. But on the other hand, it does not give rise to the escape of the vitreous humor, nor does it expose to spots, or ulceration of the transparent cornea, or prolapsus or excision of the iris, nor to the immediate destruction of the eye. On the following day the puncture which it makes is closed, and the conjunctiva, which in a majority of cases is but slightly inflamed, ordinarily resumes its natural appearance at the expiration of from eight to twelve days. Finally, we may if necessary apply it to all cases, and repeat it one or several times upon the same organ, without incurring the risk of any great danger to the patient.

III. After this enumeration it would appear at first view, that depression ought to have the preference over extraction. A rigid examination, however, does not permit us to come to a conclusion so clear and positive. It is true that the puncture of the sclerotica, choroid, retina and vitreous body, rarely produces more pain than the section of the cornea, when we proceed in the manner I have pointed out. The wounding of the nerves, and vessels of the ciliary body, is easy to be avoided, and generally attended with no unpleasant circumstances. When the crystalline capsule is properly lacerated, we cannot see why secondary cataract should be more common after depression than after extraction. If the crystalline is securely fixed in the vitreous humor, it is difficult for it to reascend or for its presence to disturb the retina. With skill also we may succeed in avoiding the iris, which the needle moreover never wounds as seriously as the keratotome. But we should be wrong in maintaining that this method is more simple and more easy than the other. It is not so easy as some persons imagine to pass the instrument between the uvea and the cataract; not to get it entangled between the crystalline and its envelope; to make the proper opening into the capsule; or to hinder the opaque body from being reversed, either upwards or downwards, should the concavity of the needle press it ever so little more in one direction than another, or be deviated from the direction indicated, or that the lens shall have contracted adhesions with the surrounding parts; finally, it is not until after prolonged trials that we are enabled to detach it and fix it at the bottom of the eye. The greatest degree of address, therefore, is indispensable to perform depression in such manner that it may have every possible chance of success. If inexpert surgeons generally prefer it, it is less owing to its apparent simplicity, than because it does not allow their mistakes to be so clearly noticed as the method by extraction. On the other hand, the irritation which it produces augments the secretion of the humors, and soon creates in the eye a feeling of distension which does not take place in the other method. A chronic or acute iritis, and afterwards a contraction and even a complete obliteration of the pupil, may frequently be produced by it. The lesion of the vitreous humor, without being immediately dangerous, may not however be altogether free from inconveniences.

The crystalline, which in fact disappears sometimes by absorption or dissolution, still more frequently remains with all its usual form and size during the space of years, and even during the whole life, whatever the moderns may have said of it to the contrary, on the authority of Pott, Scarpa, and Dablin, (*Biblioth de Planque*, t. III., p. 341, in 4to.) who, in the year 1722, had ascertained its absorption, and concluded that this always took place after depression. Beer has seen it reascend at the expiration of 26 years. Out of twelve patients whose eyes I have had it in my power to examine after death in the different hospitals, at one year, two years, two years and a half, and four years after the operation, it had scarcely diminished a fifth of its size in the only subject in whom it was perceptibly altered. In the others it had ultimately, by means of some lamellæ of the hyaloid tunic which separated that coat from it, contracted adhesions with points of the retina and choroid, which themselves exhibited a sort of knot or cicatrix of about three lines long. M. Campagnac, who has made special researches upon this point of practice, also asserts that after depression the crystalline lens is far from disappearing as speedily, and especially as constantly as had been supposed. This therefore, it must be allowed, is a serious inconvenience, one which no argument can extenuate, and which will always render the operation for cataract by depression less *complete* than by extraction.

IV. *Keratonyxis*, which Dr. Wedemeyer rejects after having made trial of it in fifty-three instances, would succeed no better, and whatever M. Schindler, who defends it, may say of it, it would be an objectionable mode of giving confidence to practitioners by penetrating after the manner of this author, through the centre of the cornea, instead of passing through the depending point of the anterior chamber. The crystalline, after it has escaped or been abandoned in front of the iris, whether in mass or in fragments, is far from being dissolved there as speedily as some authors assert. Observations collected by M. Plichon at the Salpêtrière, prove that it then often forms there a foreign body, and that if we do not hasten to remove it the eye is exposed to serious dangers. Another defect still more grave is the following: the pupil may remain movable and perfectly uniform, the whole organ have an appearance of the most perfect integrity, but the vision nevertheless be totally destroyed. I have seen four persons at the central bureau, who were blind from this cause, and who had been operated upon at Paris. A man sixty-two years of age, whom I had operated upon in 1829, at the hospital of St. Antoine, came to consult me in 1831. At first view one would say that his sight was perfectly free. The pupil is of a beautiful black, round, regular, movable, nor abnormally contracted or dilated, yet nevertheless the blindness is complete. What has imposed upon the partisans of depression is this, that the patients quite frequently appear to recover their sight after the expiration of a certain time, and preserve it, in fact, during the space of one or two months, but afterwards find that it gradually becomes enfeebled, and that the vision is totally destroyed in less than a year. If the operation, repeated seven times in one case, six times in another, and in a third as often as thirteen times on each eye, enabled Hey to cure his pa-

tients, it is nevertheless true that these repeated attempts prove unsuccessful in a majority of cases. The truth is, however, that their consequences are generally not very serious. After depression, particles more or less opaque almost always remain or are formed in front of the vitreous body. Experience proves that after extraction this accident is infinitely more rare. As to this last method it is evident, that the section of the cornea is much more delicate than the perforation of the sclerotica; that in spite of every precaution the vitreous body may escape, and the iris be extensively divided by the knife, or separated or torn by the crystalline; but after all, if the operation is well performed and the patient in a favorable condition, three accidents, the escape of the vitreous body, the suppuration of the eye, and the consecutive opacity of the cornea, can alone render it dangerous; while all other things being equal, it procures without question a result either immediate or definitive more satisfactory than the method by depression. It is requisite to state, however, that the escape of the crystalline again exposes to two other accidents. Though largely dilated by the action of belladonna, the pupil almost constantly contracts so much as to oppose a certain degree of resistance to the opaque body, which then has a tendency to detach the iris from below, in such manner as to make its escape there if the pressure upon the eye has not been made with an extreme degree of caution. This pressure in its turn, if made quickly upon the cornea in consequence of some unexpected movement of the patient at the moment when the border of the cataract presents itself at the wound, may thrust back the lens above the vitreous body; in such manner that we may remain in doubt whether it is still in the eye, or if it has actually escaped, as has happened to me in one instance.

V. *The prolapsus of the iris*, which often occurs after the operation, and more frequently in old men, in consequence of the cornea in them being tardy in cicatrizing, is treated by mechanical means or belladonna, so long as there is no adhesion; in the contrary case, by nitrate of silver; and is not more difficult of cure here than under any other circumstances. When our object is to leave no obstructing particle in the eye, there is no objection to throwing up through the wound one or two injections of tepid water with a small Anel's syringe. Perhaps even it would be really advantageous to imitate Forlenze and to adopt this method generally. Finally, if the dangers of extraction are more serious and more apparent, those of depression are more numerous and more real. Operators alike skillful will more easily avoid the first than the second, and if the employment of the needle less frequently fails of procuring some relief to the patient, the method of Daviel furnishes by compensation a greater amount of radical cures. Find a way to avoid the suppuration of the cornea, and extraction will obtain a large amount of cures; prevent iritis after depression, and the patients, though free from suffering or danger, will nevertheless run the risk of obtaining but imperfect results from the operation. Out of 300 operations for cataract whose cases I have minuted, I count 200 cures. In the hospitals where I have adopted sometimes extraction above or below, sometimes depression by different methods, I am still uncertain to which method I ought to attribute the greatest amount of advantages or inconveni-

ences. In private practice, extraction evidently succeeds better. I conclude therefore that under circumstances where the two methods might either of them be indifferently made trial of, extraction is preferable; but that in other cases, it is sometimes one and sometimes the other which should be adopted. Depression, for example, appears to be preferable in children and intractable subjects; or when the eyes are small and sunk deep in their sockets, when the cornea has spots upon it and is small and flattened, when the eyelids or conjunctiva have been for a long time diseased, when we have reason to fear an acute inflammation of the connecting tissues of the eye, when the cataract is perfectly liquid, when the pupil is contracted or the iris adherent to the cornea, and when the eye has great prominence and is very irritable. Extraction, on the contrary, presents more advantages in old men and even in adults, if the anterior chamber is large, the crystalline very hard, the cataract membranous or adherent, and the eye perfectly sound, possessing little sensibility, and admitting the keratome to penetrate through it without difficulty.

[*Ossified Crystalline Lens.*—The *crystalline lens* having become opaque from a blow in a man aged 44, (see Mr. France in Guy's *Hospital Reports*, Oct., 1845,) was afterwards extracted and found to consist chiefly of *carbonate and phosphate of lime*. T.]

#### [CATARACT.

Dr. Dubois, of Neuchatel, in Switzerland, (*Gaz. Méd. de Paris*, Nov. 8, 1845, t. XIII., p. 72f.) removed in July, 1841, by depression, a cataract which was situated in the right eye of a woman aged 49, accompanied with a slight albugo in the cornea, both of which had existed for the space of 40 years. She was induced to undergo the operation from a cataract having commenced to form also on the left eye, in 1841, which when ripe the succeeding year was also removed. This left eye being, from its long use, fully developed, could now see better than the other, where a contrary state of things existed, with the addition of the partial opacity of the cornea, which still presented some obstruction to vision. Doctor Tavignot remarks (*Ib.*, *loc. cit.*, p. 720) that disuse of the eye for a long period undoubtedly arrests its development, and that on this account persons a long time confined in dark places (as in dungeons) lose the sensibility of the retina, and thus become liable to amblyopy, or even to amaurosis. But the condition of the eye, where a cataract complete has existed in both organs for a great number of years, is not precisely, or at least is only partially analogous to that which takes place from the total exclusion of light from *sound* eyes. In old cataracts, the retina still retains its sensibility to a certain extent, and receives a certain portion of the rays of light transmitted through the opaque lens. Hence the important deduction that such cataracts, however ancient, as recent facts have proved, are not beyond the hope of surgical relief. Dr. Tanchou alludes to the remarkable case of a man aged 67, in whom M. Serre, of Montpellier, operated with entire success in 1844, for a cataract which had existed in the left eye for *sixty years*. (*Gaz. Méd. de Paris*, t. XIII., 1845, October 25, No. 43, pp. 677, 678.) The occasion which led to the operation was a traumatic cataract, which suddenly formed in the *right* eye,

accompanied with protrusion of the iris through the cornea. On examining the left eye, he found there a lenticular cataract, with a slight albugo in the cornea. Deeming this the most secure, he hazarded the operation in this eye, when the sight was restored perfectly. Dr. Taignot furnishes a number of examples of the cure of old cataracts, single or double, congenital or otherwise, and which had existed for various periods from 12 to 20, 26, 30, and even 45 years. Dr. Alexander Watson, of Edinburgh, (*Ed. Med. and Surg. Journ.*, Jan. 1, 1846, p. 57, &c.,) considers that the process of breaking up *soft* cataracts, in order to promote their solution and absorption, as now practised and in vogue, is so eminently successful, that it promises to be substituted altogether for depression or extraction in this form of the disease. For hard cataracts, and where depression or displacement is decided upon, he recommends a process somewhat new, and the intention of which is to avoid any injury to the hyaloid membrane and iris, and to prevent the reascending of the lens. As the important point is to disengage the lens from its capsule before depressing it, this is to be effected by lodging it in a breach to be first made with the needle in the vitreous humor, after which the posterior part of the capsule opposite this breach is to be carefully opened by an incision, and the lens also pushed through it into the humor by means of the same needle. Dr. Watson penetrates the coats of the eye at a line and a half posterior to the margin of the cornea, with the small cataract bistoury. This brings him readily upon the part of the vitreous humor designated. After making a suitable breach there, the needle incises the posterior portion of the capsule transversely from the nasal side outwards. The point of the needle is then applied flatwise on the anterior part of the capsule, between it and the iris, so as to make pressure upon the lens upwards and backwards, in order that the lower margin of the lens may pass backwards through the opening in the posterior portion of the capsule; after which, by shifting the point of the needle forwards upon the lens, the latter is pushed backwards and downwards into the breach of the vitreous humor, from whence, he says, *it never rises*. If the capsule remains entire, it is an advantage, as the humors in the different chambers of the eye are thus prevented from incorporating, which lessens the risk of subsequent inflammation, and if it should afterwards become opaque, it can easily be removed by a subsequent operation. Address is required for this operation, as the capsule is usually transparent. This process answers also for reclination. If the lens should unexpectedly be found to be soft, it can be broken to pieces, and these fragments, or some of them, pushed into the breach of the vitreous humor, where they will dissolve. The breaking up of an *opaque lens*, that it may dissolve in the aqueous humor, and performed in such manner as not to wound the hyaloid, is a process well suited to young subjects, whether the cataract be spontaneous or from an injury. For keeping the eyelids open, Dr. Watson finds a plain, broad, flat, smooth ivory hook, the end of which is curved short, so as to be parallel with the shaft, better than metallic instruments. T.]

F. *Artificial Cataracts*.—For a long time it has been thought necessary to produce cataracts artificially, and to exercise ourselves

beforehand upon animals or dead bodies, and to give moreover to the eye all that mobility which renders it so difficult to steady it at the moment of the operation. Troja in Italy, and M. Bretonneau in France, have made trial of some experiments in order to render the crystalline opaque, by means of diluted acids. M. Leroy, (D'Etiolles,) has supposed that this could be effected better by means of electric discharges, but nobody before the time of M. Neuner of Darmstadt, (Maunoir, *Thèse citée*, p. 43,) had made this point a subject of particular attention. The liquid which he made use of with most success, was a solution of six grains of corrosive sublimate in one gros of pure alcohol. A small glass syringe, garnished with platina and terminated by a very fine syphon, and which is traversed by an extremely sharp probe, in such manner as to be enabled to pass beyond its two extremities, is first filled with this solution. It is then passed through an opening previously made at the outer angle of the eye, from above downwards, from without inwards, and from behind forwards, until it reaches the posterior surface of the crystalline, into which the point of the probe, which serves as a conductor to the syphon of the syringe, is plunged, after having perforated its capsule. The small probe being then no longer necessary, is withdrawn, and the thumb, resting upon the extremity of the piston, gently forces the liquid into the substance of the lenticular body, which soon changes its color. The same process is performed, if necessary, on the inner angle of the eye, when the operation is terminated. Among the contrivances devised for representing upon the eyes of the dead subject, the principal difficulties which are encountered upon living man, the ophthalmo-phantome of M. Sachs, is certainly the most ingenious; composed of a socle mask, and eye-supporter (*porte-œil*), the description of which I cannot give in this place, it appears to me, however, to be too complicated ever to be received into general use. I have no necessity in saying, that one of the middle refractors of the eye being now removed or displaced, almost every individual who has been operated upon for cataract, ought to wear spectacles with convex glasses, like long-sighted persons. Upon this subject, moreover, Maitrejan had established upon the dead body, what M. Roux and others have since announced—to wit, that after the extraction of the crystalline, the vitreous body becomes more convex in front, as if for the purpose of filling up the void, which after the operation has been left in the eye, and to render spectacles less necessary. In children, and in persons blind from birth, in all those in fine who for the first time are obliged to subject their sight to a course of discipline, it is well to add to the precautions which are generally used, a very simple means successfully employed by Dupuytren, and which consists in fixing the hands behind the back, in order that being deprived of the use of these members, they may be compelled to make greater efforts with their eyes to direct them upon external objects.

#### § IV.—*Artificial Pupil.*

Two very distinct conditions of things may require the formation of an artificial pupil; the opacity of the cornea, and the contractions or obliteration of the natural pupil. In the first case, whether

the impediment to vision be the result of a simple ophthalmia, an ulcer, or a wound, or any other lesion of the cornea, is a matter of little importance. Provided the interior of the eye is not affected, and that a transparent point remains outside, the operation for artificial pupil may be undertaken. In the second case, whether there be myosis or phthisis, synechisis or atresia; whether the pupil is completely closed or merely contracted; whether the alteration be congenital or accidental, the effect of an internal ophthalmia, of an iritis, or of the operation for cataract, by depression, or extraction; whether the iris preserves its form or not, adheres, or is not adherent to the cornea or the capsule of the crystalline; or whether there may or may not be sinechia, whether anterior or posterior, the operation is equally practicable, (though it offers infinitely less chances of success,) so long as the retina has not lost the faculty of perceiving the rays of light, and that the anterior chamber retains its transparency. If this last condition is wanting, it will be in vain that we make a new pupil, and that the light arrives at the bottom of the eye. Acute or chronic inflammations of the internal tunics, the progress of which has not been definitively arrested, also constitute counter-indications, which, though less absolute, are nevertheless sufficient with a few exceptions to restrain a prudent surgeon. Almost all authors prohibit, moreover, the making of an artificial pupil, so long as there is but one eye only diseased, and that the patient sees sufficiently well to get along without a guide. The operation, in fact, being sometimes followed by accidents, which may in themselves produce serious injury to the vision, it would not appear to be prudent to expose the patient to lose the little that remains to him, when, moreover, in the attempt to ameliorate his condition, the chances of success are sufficiently precarious.

A. *Operative methods.*—All the processes recommended for forming a new pupil may be resolved into three methods. In one, *iridiotomy* or *coretomy*, we incise the iris only; in the second, *iridectomy* or *corectomy*, we excise a flap from this membrane; while in the third, *iridodialysis* or *coredialysis*, we confine ourselves to detaching its circumference at one of its points.

1. *Coretomy or method by incision.*—Before the time of Cheselden, no one spoke of iridiotomy; since then it has attracted the attention of Mauchart, Sharp, Sprægel, Meiners and Rathleav, who have proposed it in cases of persistence of the pupillary membrane; and of Odhélius, Guérin, Janin, Wenzel, and MM. Maunoir, Adams, &c., who have subjected it to various modifications. The patient, operator, and assistants, are to be placed in the same manner as in the operation for cataract.

a. *Process of Cheselden.*—By means of a small knife of the shape of a scalpel, with one cutting edge only, Cheselden penetrated in the same manner as is done for depression through the sclerotica as far as the uvea. Having arrived there, he caused the point of his instrument to pass into the anterior chamber. Afterwards directing it from without inwards, and from before backwards, according to some, or on the contrary, according to others, from the internal to the external angle, and from behind forwards, he made at the centre of the iris a transverse incision of from two to three lines in length. A

pupil of an elliptical form, similar to that of certain quadrupeds, was the result of this delicate operation, which was attended with entire success, and vividly attracted the attention of the learned world.

*b. Process of Sharp.*—Sharp in performing coretomy, professes nothing else than to have imitated Cheselden. A small scalpel, slightly convex on its back, a figure of which he gives, is first directed horizontally, its cutting edge turned backwards, into the posterior chamber, between the circle and root of the ciliary processes. Nothing then remains but to incline its point forward, and to push it a little in order to penetrate into the anterior chamber. We have now to incise the iris transversely, either upon a line with or below, or what is better, above the natural pupil. The opening made by this operation, which continued for some time, was not long in contracting, and ultimately closed up completely. Sharp thus appears to accord very little confidence to the method of Cheselden.

*c. Mauchart* has no other claim to be mentioned in this place, except because he appears to have been the first to have advanced the idea of perforating through the cornea in order to form the pupil. He moreover cautions us against giving too great an extent to the artificial opening, and remarks that this kind of pupil is not capable either of spontaneous dilatation or contraction like the natural one. *Henkel* also recommends that we should go through the anterior chamber. *Heuermann*, who is of the same opinion, recommends for the incision of the iris and cornea, that we should use the ordinary lancet in place of the needles or knife of Cheselden.

*d. Process of Odhélius.*—Odhélius, in a patient with an opaque cornea, after having incised the cornea in the same way as for extraction in cataract, divided the iris from its centre to the circumference, on a line with the pupil, which in other respects was very much contracted. By this means he obtained a triangular opening continuous in its base with the remains of the primitive pupil, and which enabled the vision to be completely reëstablished.

*e. Process of Janin.*—Janin, having frequently made trial of the method of Cheselden without success, supposed that we would succeed better by giving a vertical direction to the wound. The transverse incision, he remarks, closes speedily and almost of necessity, because the radiating fibres of the membrane are separated only; while they are actually *divided* by means of the perpendicular incision, made a little within the natural pupil. It was an accident which led him to make this modification. It happened to him as it would to any person, that he divided the iris in performing the operation for cataract by extraction, and that he thus made, against his will, an artificial pupil on the side of the natural one. Perceiving that this opening, which he did not intend to make, did not close up, while those which he had effected designedly always became obliterated, he proposed to take advantage of this, and directed his attention afterwards to systematizing the process which chance had pointed out to him. Kortum proposes that in place of the scissors, we should incise the iris vertically with the keratotome. But, notwithstanding the experience of Weissemborn, and the observations of Pellier, which are calculated to corroborate its advantages, the process of Janin was soon abandoned. It was soon evident that the

pupil made in this manner, does not endure any longer than, and closes and disappears fully as much as it does by the transverse method.

*f. Process of Guérin.*—With the view of uniting their advantages, Guérin proposed to combine the processes of Cheselden and Janin, and to employ them together, that is to say, to make a crucial incision in place of a simple vertical or transverse slit. But while on the one hand the operation is thus rendered much more difficult, on the other, it is not uncommon to see the four flaps approximate so much at their apex as to prevent the light from arriving at the bottom of the eye; so that this recommendation has been rarely adopted in practice.

*g.* When the vision is impeded by a leucoma, Pellier confines himself to enlarging the natural pupil, in place of making one complete in itself. For that purpose he incises the cornea in the same way as for extracting the crystalline; introduces a small canulated sound into the posterior chamber of the eye; uses this as a guide to the point of a small pair of scissors, and first divides the iris outwardly, then inwardly and upwards, from the pupil to the ciliary ligament.

*h. Process of Maunoir.*—The process by M. Maunoir, though the result of researches made by this author, nevertheless appears to be only an improvement of that of Pellier. This surgeon, by means of a keratome or lancet, makes an opening of two or three lines in extent at the outer and lower part of the cornea; introducing through this a small pair of scissors bent at an angle on the border near their heel, and one of the blades of which terminates in a button, he opens them in the anterior chamber; then plunges one branch through the iris into the posterior chamber, in such manner that the other which bears the button remains behind the cornea; incises the membrane thus included inwards, then outwards and upwards, and forms at its expense a triangular flap whose adherent base faces the circumference of the eye. The *needle-shaped scissors*, devised by M. Montain, with the view of avoiding the previous section of the cornea, though ingenious, do not however present an improvement of sufficient importance ever to obtain the preference claimed for them by their inventor. By this double incision the circular fibres that M. Maunoir supposes to exist in the iris are divided twice, while the radiating fibres remain intact; from whence it happens that these latter by their contraction constantly tend to dilate the new pupil, in place of favoring its contraction, as in the method of Cheselden.

*i.* The ideas of the surgeon of Geneva, which he has frequently, and again in 1837 (*Bibl. Universelle de Genève*, Avril, 1838) practised upon with success, have received the sanction of the celebrated *Scarpa*, who, in order to sustain them, was eager to renounce his own method. They have also met with partisans in Germany. But in England and France they have not generally been made trial of. Moreover, it is evident that if we were desirous of performing coretomy upon this principle, of which M. Carron avows himself the champion, it could be advantageously modified by making use, as I have often done, of the ordinary keratome, or the movable cutting needle, which I contrived for form-

ing the triangular flap of the iris, thus doing designedly what we often do in spite of ourselves when we perform the operation for cataract by extraction; this is the process which Daviel, Hoin and Wenzel appear to have recommended for adoption, and which Odhélius has also sanctioned.

*j. Process of M. Adams.*—M. W. Adams has gone back to the process of Cheselden, with this difference, that in place of a straight knife like that of Sharp, he employs a small scalpel convex upon its cutting edge, breaks up the crystalline when he considers it opaque, and endeavors, what is sufficiently singular, before quitting the eye, to entangle some fragments of it in the transverse incision of the iris to prevent its closing up. M. Roux frequently made use of this process while I served him as assistant, and in every case the new pupil ultimately disappeared. Nor does it appear, moreover, to have received much respect in the country of its author, for it is rare that it has been had recourse to there by other surgeons. Nor have I myself been more fortunate with it in the two trials that I have made of it.

*k. Coretomy*, still further modified by Jurin, MM. Langenbeck, Weller, Faure, and by *Wardrop*, who by means of a needle passed into the posterior chamber, perforated the iris a first time from behind forwards in order to enter into the anterior chamber; then a second time from before backwards, and nearer to the inner angle of the eye in order to return into the posterior chamber; and who afterwards united together by means of one of the cutting edges, rather than by the point of his instrument, the two small wounds, by detaching one of the extremities of the flaps which they circumscribed, and all this with entire success, in a lady 46 years of age, blind from her birth, has found in these latter years numerous antagonists among the oculists of Germany.

*l. Process of the Author.*—I make use of a knife somewhat longer and of less breadth than that of Wenzel, cutting on its two edges to the extent of four lines from its point, and afterwards blunt or rounded upon the back as far as the handle, an instrument in fact of which the *serpent-tongued* lancet may convey a tolerable idea. Held as a writing pen, it is plunged through the cornea on its temporal side, and a little obliquely from before backwards. When it has arrived in the anterior chamber, its point is guided with precaution into the posterior chamber, dividing the iris as it proceeds, and then brought back after making a track of two or three lines, into the anterior chamber through the same membrane. In continuing to advance it forward, up to the point of piercing the cornea a second time, it becomes easy to divide the species of bridge which covers its anterior surface, and not to detach completely one of the extremities of this flap of the iris, until after having transformed the other into a pedicle as narrow as may be desired. We thus procure a division which amounts to a loss of substance. The fragment of membrane which has been cut out cannot be long in rolling up upon itself, and must ultimately become dissolved in the aqueous humor. It is even possible in most cases to excise it entire, when the manipulation which I have just pointed out has been properly executed. In fact if the instrument acts in an equal manner on the two ad-

herent points of the bandelette to be divided, up to the moment when the section of one is completed, all that will be required to detach the other and to transform coretomy into corectomy, will be to advance the keratotome a little farther, and to incline its cutting edge correspondingly towards the cornea. My *keratonyx* attains this object still better.

II. *Coredialysis or Method by Décollement*.—To Scarpa we are indebted for having systematized *décollement* into a method; many authors, however, had mentioned it before him. Sharp for example, in speaking of coretomy, makes the remark that the iris very frequently detaches itself when pressed upon by the instrument in place of being divided. In a patient operated upon for cataract by Wenzel, the crystalline escaped in this manner through an accidental opening. The natural pupil afterwards almost entirely disappeared, but the patient continued to see by the abnormal opening. If we may believe Assalini, Buzzi de Milan, who performed coredialysis in 1788, plunged a spear-shaped needle through the posterior chamber into the body of the iris, at a line distant from the obliterated pupil, and by well directed tractions detached this membrane from the ciliary circle. A. Schmidt, who on his part published a good memoir on this subject in 1803, states that he had recourse to this operation in 1802, and had conceived the first idea of it in 1792.

a. *Process of Scarpa*.—Scarpa, when his needle has reached into the interior of the eye, as in the operation for cataract by depression, turns its concavity forwards; directs it behind the upper and inner portion of the uvea; pushes its point through the iris into the anterior chamber; and uses it afterwards as a hook in oscillating it from above downwards, from behind forwards, and from within outwards, in order to detach the great circumference of this membrane to the extent of three or four lines, in such manner in fact as to procure an opening a slight degree larger than the natural pupil.

b. *Process of T. Couléon*.—Toché-Couléon, one of the first, Flajani, Himly, Beer especially, and Buchorn, proposed that the needle, whether straight or curved, should be directed in some way or another through the cornea, and not through the sclerotica. According to them, it becomes full as easy in this manner to place the new pupil upon the out as upon the inside; moreover, we see better what we are doing, and the puncture of the eye must be less dangerous.

c. *Process of Assalini*.—Assalini, after having made an incision at the outer angle of the cornea, introduces into the anterior chamber a pair of fine curved forceps, soon after opens them, seizes the iris at a short distance from its ciliary border, and detaches it as in the process of Scarpa. These forceps are considered useless by Bonzel, who substitutes for them a very small hook, which is conducted in the same manner. Dzondi makes use of a description of forceps, the inner side of one of whose branches is to be grooved in order to receive the other when the instrument is closed. He pretends that with this forceps we run no risk of lacerating the iris, and that by it it is more easy to effect *décollement* than with any other instrument. The strongest and best founded objection to be made against coredialysis is, that the detached border of the iris gradually reassumes its natural posi-

tion, and that, at the expiration of a certain time, the new pupil almost always closes.

*d. Process of M. Langenbeck.*—To obviate this inconvenience, M. Langenbeck, after having seized hold of the iris by means of a small hook protected in a sheath, draws it forwards and insinuates it into the wound of the cornea, which should be very small, and then attaches it there as if for the purpose of producing a *myocephalon*. The adhesions which this species of hernia soon contract prevent the pupil which has been formed from narrowing, and give to the operation all the certainty desirable.

*e. Reisenger*, who advances the same idea, censures the sheath-hook of Langenbeck, and makes use of a simple eye-forceps, the point of which is curved like an erigne on one of its sides. This forceps is introduced flatwise, and shut to the farthest limits of the anterior chamber. Its concavity is then turned backwards. It is opened the space of one or two lines, to be closed again after having plunged it through the iris, which membrane is thus found pinched or hooked up, and is then detached and drawn to the outside in order to produce an artificial prolapsus through the cornea. The *coreonction*, so much extolled by M. Graefe, is used in the same manner as the sheath-hook of M. Langenbeck, and differs from it scarcely except in the little keratotomy which it has on one of its extremities.

*f. Process of M. Lusardi.*—M. Lusardi has proposed to reduce coréodialysis to its greatest degree of simplicity, by devising a hook-shaped needle which alone would answer for the whole operation. When closed, this instrument has the form of a Scarpa needle, or rather of a very small serpette. The two stems which compose it are arranged in such manner that, by drawing a little upon the shortest or that which corresponds to its convexity, there immediately results from it a notch which transforms it into an actual forceps. It is introduced through the cornea in the same way as in keratonyxis, in order to pass it through the anterior chamber, if that is free, or in the opposite case through the posterior chamber, after having cut through the iris up to the ciliary circle. Having arrived there, the surgeon presses its back against the great border of the ocular diaphragm, which he endeavors to detach by means of an oscillatory movement, then opens his needle, and afterwards loosens its spring, by which means the membrane is thus found embraced. Nothing remains but to bring it to the opening of the cornea, with the precautions required for giving to the new pupil the necessary dimensions.

*g.* With this instrument, already described in Italy by Donegana and Baratta about twenty years since, M. Lusardi thinks we run no risk of wounding the capsule of the crystalline, which is not demonstrated, and that we may be enabled to establish an artificial pupil upon any point whatever of the ciliary circumference, which is more correct; but the ordinary needle presents nearly the same advantages. I do not speak here of the process of Assalini, which, in order to remove the new pupil as far as possible from the crystalline, proposes that in coréodialysis we should destroy a portion of the ciliary circle and processes, at the same time that we detach the great circle of the iris.

This method clashes so much with the object which the practitioner has in view, that no surgeon has ever yet had recourse to it.

*h. The process of Donegana* is not obnoxious to the same objection. Perceiving that the pupil, after coredialysis by the method of Scarpa, almost always finished by closing up, this oculist has proposed, in order to prevent such an inconvenience, that we should unite the method by incision to the method by décollement. He therefore, after having detached the iris from the sclerotica, divides it to the extent of one to two lines, in a direction parallel to its radiating fibres, and from its greater to its smaller circumference. For that purpose we may penetrate through the posterior or anterior chamber, and make use of the ordinary needle, or of an instrument with a blade which is somewhat more slender, almost straight, and very keen. Unfortunately it is not so easy as might be imagined to incise the iris after having detached it in the interior of the eye. Unless we make use of the keratonyx, it folds itself up under the knife, and tears or separates itself from the surrounding parts, much sooner than it is divided. Nevertheless it is an improvement which may have some advantages, and which it would be advisable to make trial of when we perform coredialysis according to the method of Scarpa.

III. *Corectomy, or the method by Excision.*—*a. Wenzel* appears to be the inventor of corectomy. Nevertheless it cannot be denied that before him it was put in practice by Guérin, who, as Sprengel remarks, sometimes excised the point of the flaps of his crucial incision. Sabatier, who adopts the process of Wenzel, gives the most satisfactory account of it. We proceed in the same manner at first as for the extraction of a cataract. The keratotome, while passing through the eye, ought to cut out, at the expense of the iris, a flap similar to that of the cornea. A pair of small scissors are then introduced into the anterior chamber, and serve to excise this flap near its base, while the point of it moreover, if necessary, is seized with a pair of eye forceps. By this means we obtain an opening with loss of substance, which cannot be closed up, and which presents every possible chance for success.

*b. Demours*, however, adopted a mode somewhat different in a case of leucomatous cornea. He made an incision into the anterior chamber, which comprised at the same time both the cornea and the iris; then with two cuts of the scissors, he circumscribed and removed a flap of this membrane of the size of a sorrel seed. The difference between these two modes is in reality very trifling. The first has some advantages, in the fact that it enables us to confine ourselves to corectomy, if we should prefer this after having commenced, but the second evidently exposes us to less risk of emptying the eye. It is from one of these processes, moreover, that are derived the principal methods extolled by the oculists of our time.

*c. Process of T. Couléon and of M. Gibson.*—*M. Gibson*, like Wenzel, first opens the cornea to as great an extent as for extracting a cataract, but without touching the iris. He then causes this membrane to protrude through the wound by means of a slight pressure made upon the globe of the eye; then by means of scissors, properly hollowed and curved on their flat side, he excises a disc

from it of suitable size. Forlenze has no fear of incising the cornea to the extent of two-thirds of its circumference, in order to seize the iris with the forceps or hook, and to remove a flap from it in the manner of Demours. In a thesis supported in 1803, M. Mirault gives the credit of a similar process to Couléon.

*d. Beer* asserts that all that is required is to make an opening of two lines in the anterior chamber to make the iris protrude of itself into this small wound, when the part which tends to escape outside may be immediately excised. Otherwise he seizes this membrane with an erigne, and effects its exsection as in the preceding cases.

*e. Process of M. Walther.*—M. Walther, with a view no doubt of reconciling the principles of Gibson with those of Beer, incises the cornea to the extent of about three lines, draws the iris to the outside by means of a hook, and by means of a small pair of scissors excises a flap from it of the proper dimensions. By means of a wound of nearly the same dimensions, M. Lallemand has found that he could seize the membrane with a small pair of hook forceps, draw it towards him, excise from it a flap of considerable size, and form in this manner an elliptical pupil like that of cats, vertical in its position, and two lines in breadth and six in length. The success in one case, says the author, was so complete, that the patient was enabled to follow the army of Spain in the capacity of a nurse.

*f.* The needle forceps of Wagner, and of Dzondi; the *raphian-kistron* of Emden; the *iriankistron* of Schlagintweit; the *plomise* of Menser, and the process of Himly, do not differ sufficiently from some of the instruments and processes described above to make it necessary for me to detain the reader with an account of them.

*g.* I will make the same remark of the method of *Autenrieth*, which consists in destroying a portion of the sclerotica and of the ciliary circle and processes, and removing a disc, in a word, of the globe of the eye outside the cornea, with the simple precaution to close up the opening which has resulted with a flap of the conjunctiva, which should have previously been separated from it. The best that can be done in reference to such a suggestion, is to say nothing of it, and I am astonished that Beer, Himly, Müller, Guthrie, Ammon and Ulman, (Nimmo, *Arch. Gén. de Méd.*, 2d ser., t. III., p. 237,) should have gone to the trouble of making a trial of it.

*h. Process of Physick.*—Physick, after having incised the cornea and iris, in conformity to the precepts of Wenzel, introduces into the anterior chamber a forceps terminated by plates, in some respects similar to those of our chimney tongs. The inner surface of these plates presents upon its circumference a cutting edge, which forms a scissors of peculiar description, and by means of which it becomes easy to seize hold of and remove the flap of the iris which has previously been cut out by the keratotome.

*B. Relative value of the different Methods.*—I. These numerous processes show at least the constantly reiterated efforts of practitioners, to improve one of the most delicate operations of ocular surgery. Unfortunately there are often to be encountered here obstacles and difficulties, which the greatest address and most consummate skill are incapable of surmounting. When rigidly examined there can be no doubt that corectomy is preferable to the other two methods.

Nevertheless since, in order to perform it, it is necessary that the instrument should traverse the anterior chamber, it is next to impossible to have recourse to it, when the iris adheres to the cornea, or when this last membrane is opaque throughout a great portion of its extent. Coretomy presents nearly the same inconveniences without having the same advantages, since, as experience has demonstrated, the opening which it makes rarely endures beyond a few weeks. It is to coredialysis, therefore, that we should then give the preference. The same would be the case in instances of *adherent membranous cataract*, in those of any description of *opacity* whatever, situated in front or *behind the iris*, and which could not be destroyed, inasmuch as we are here obliged to bring the pupil to the circumference of the ocular diaphragm.

II. Coretomy and coredialysis alone enable us to operate by *scleroticonyx*. Nevertheless, as they may also be performed by *keratonyxis*, we ought not, as a general rule, to prefer the first, except in strongly marked cases of anterior synechia, (*sinéchie*,) inasmuch as we almost unavoidably wound the crystalline. Should we be disposed to restrict ourselves to coretomy, but not to employ the process which I have proposed, that of M. Maunoir, or better still that of Wenzel, would appear to me to merit the preference. To perform coretomy, we may adopt, so to speak, indifferently, the process of Demours, Forlenze, Gibson, Beer, or M. Walther, though the best of all, in my opinion, would be that of Physick, such as I have modified it, or the *iridectum* of M. Onsenort, if it were possible to procure a sufficiently small punch, and one that was perfectly constructed; which, up to the present time, I have not been enabled to obtain.

III. When we decide in favor of coredialysis, the simple hook of Bonzel is quite as good as the more complicated instruments of Langenbeck, Beer, Reisinger, &c.; but I doubt if it be as easy as these authors seem to imagine, to attach in the opening of the cornea, the portion of the iris which has been brought there with more or less difficulty. Should the accident for which we desire to establish an artificial pupil have taken place as the consequence of an operation for cataract, there would be much less inconvenience here than in the other cases, in directing the instrument through the posterior chamber. In such cases, also, the bottom of the eye is too much altered to leave room to hope for much success. Nor can we perceive that it would be necessary to open into the anterior chamber as largely as has been recommended by Wenzel, Forlenze, and Gibson. It would be otherwise should the crystalline or its capsule have preserved their natural relations.

However little we may suspect opacity in these parts, they should be extracted or depressed. Perhaps, also, their extraction or their displacement should be laid down as a law, whether opacity has commenced or not. We should thus avoid the unpleasant consequences of the occurrence of a consecutive cataract, destroying the prospect of success for the first operation, as happened to me in the case of a man aged thirty years. In this respect, the opening of the cornea cannot be too large, since we not only establish an artificial pupil, but perform at the same time an operation for cataract.

IV. When there are *spots in front of the eye*, and that we cannot operate by keratonyxis, the case necessarily becomes embarrassing. If the incision is made on a sound part of the cornea, the cicatrix which must result from it, and the inflammation which may supervene, very frequently destroy the transparency of the small portion which the primitive disease had respected. Upon the leucomatous portion on the contrary, it is to be apprehended that the wound may be transformed into an ulcer, and suppurate and cause the destruction of the eye. Nevertheless many practitioners, MM. Faure and Lusardi among others, have asserted that the section of a cornea thus affected, is not as formidable as is generally thought, and go so far as to say that it agglutinates more rapidly than that of a tunic which is not diseased. This also may readily be conceived. Such tissues being less sensitive, less excitable and more approximate in their character to vegetative life, must be more moderate in their inflammation, than if they were in their normal state. If then, the cornea is opaque to a great extent, we must cautiously respect the part that remains, and penetrate through its altered portion. In the opposite case, when its transparency is not affected but by a spot which is accurately circumscribed, and of little extent, it is preferable to incise in the natural tissues.

V. Moreover, in order to be prepared to meet all the necessities and exigencies of the disease, it is well to familiarize ourselves with the greater part of the processes which I have deemed it advisable to point out, since there are cases in which each of them may become particularly applicable. I would however remark, that the method by excision is in fact the only one which presents real chances of success. All the methods by incision, whether simple or complex, are decidedly bad, and ought not any more than décollement to be adopted, unless as an exceptionable resource. I have performed the operation for artificial pupil according to the precepts of Scarpa, Wenzel, and M. Maunoir, and I have noticed that the opening in the iris, after having remained sufficiently large during a certain space of time, has almost constantly become ultimately reduced to a trifling affair. I performed it in a young girl by the process of Odhélius, and although the slit at first appeared very large, it finally became contracted to a considerable degree.

VI. These facts, and the wounds of the same membrane, during the operation for cataract, have moreover satisfied me that the different processes suggested by the alleged muscular nature of the diaphragm of the eye repose on a false basis. In place of retracting itself towards its root, the flap which I made in the iris in 1829, at St. Antoine, in a man sixty years of age, gradually approximated on the contrary, by its free border, to the point from which I had separated it. The same thing occurred to me in 1831 at La Pitié; and I have lately had a similar instance following the extraction of a cataract. Here is another example which appears to me entirely conclusive. A peasant 45 years of age, was operated upon by me at La Pitié, in the month of June, 1831. On one side the iris slipped under the edge of the knife, and I removed a flap from it which left a notch, one line deep and two in breadth, and a little nearer the ciliary circle than the pupil upon the border of which it was made. But in place of be-

ing transformed into a large oval opening, and becoming deformed, the circle of the pupil absolutely lost nothing of its regularity.

It continued to dilate and contract as before, to such degree that its two extremities appeared to be drawn towards each other, as if to establish its continuity, rather than having a tendency to retract outwards, or to be withdrawn towards the great circumference of the membrane, and to become confounded with the bottom of the notch. M. Graefe (*Arch. Gén. de Méd.*, t. XXI., p. 271,) states that he has five times performed the operation for artificial pupil with success, and M. Eckstrumer (*Bull. de Fér.*, t. VIII., p. 203) appears to have been not less fortunate in three of his patients; I have succeeded with it but twice. M. Laugier, (*Bull. de Therap.*, t. VIII., p. 380,) by introducing a needle through the cornea, has succeeded in destroying the adhesions which kept the pupil contracted. I was no less fortunate in 1835, in a patient of M. Requin. This method, which was so much extolled at first by M. Silvy, (*Mém. de l'Acad. de Méd.*, t. IV., p. 445,) for cases of obstruction and contraction of the pupil from the debris of a cataract, would be better adapted for the obstructions caused by inflammations of any kind, as pointed out by M. Siméon, (*Revue Méd.*, 1828, t. III., p. 126,) and wherever opaque flaps or adhesions should mask the pupil, or keep it immovable. I will add, that in such cases scleroticonyxis, by enabling us to depress false cataracts with greater facility, would be preferable to keratonyxis.

C. *Consequences of the operation.*—After the operation the patient is to be submitted to the same regimen, and treated with the same precautions as if he had been operated upon for cataract. Nevertheless, the accidents that follow are rarely as severe. Should we confine ourselves to keratonyxis, or even to scleroticonyxis, they are often reduced to inflammatory symptoms of the most unimportant character. If the eye has not completely, or for a great length of time, lost the function of perceiving the light, very frequently the patient, under such circumstances, may dispense with keeping his bed, and wear only a black silk bandeau during the space of a few days. The lady operated upon by Wardrop was enabled to re-enter her carriage immediately after, and without any inconvenience. An intractable patient, whom I could not restrict to any systematic course, got up on the evening of the same day of the operation, and on the following day was indisposed to make any retrenchment in his diet or occupations, yet not the slightest inflammation supervened. Out of seven other individuals whom I have operated upon, none of them experienced any inflammatory symptoms. When, however, we perform keratotomy and largely open into the cornea, like Wenzel, &c., and when we have deemed it necessary to extract or displace the crystalline or its connections, and when the natural pupil has been completely closed for a long time, it would be imprudent not to proceed in the same manner precisely as after the operation for cataract. In all these cases, as that of M. Lallemand, (*Arch. Gén. de Méd.*, t. IV., p. 69,) for example, demonstrates, the most intense ophthalmia may be readily developed. Out of an aggregate of 18 operations for artificial pupil, I have obtained only three successful results, but none of the patients were attacked with

any severe accidents. Moreover, we ought not to be apprehensive of giving too great an extent at first to the opening into the iris, for besides that the new pupil for a long time retains a great tendency to contract, we have now the proof that the absence of the iris does not abolish vision. M. Hentzchel (*Lancette*, t. V., p. 440,) relates the history of three sisters, in whose eyes this membrane was wanting, but who could, nevertheless, see very well. The same was the case in the child six years of age mentioned by M Stoeber, (*Journ. de l'Institut.*, 5th year, p. 394,) and with the persons whom I have elsewhere mentioned, (*Dict. de Méd.*, Art. *iris*, 2e edit.) I have already seen in eight or ten instances, one, or even three accidental pupils in the neighborhood of the natural one, without its being productive of the double vision mentioned by Righellini, (Portal, *Hist. de la Nat.*, &c., t. V., p. 480.) If we have to operate to remedy the consequences of an internal ophthalmia, we must be prepared to meet with a sort of true or false cataract behind the iris, and adopt measures to remedy this difficulty or destroy its effects.

### § V.—*Puncture and Incision of the eye.*

Formerly puncture of the eye was made use of in *onyx*, or effusion of pus between the lamellæ of the cornea, in *hypopyon* or abscess in the anterior chamber, in *empiesis*, or abscess in the posterior chamber, in *hydrophthalmia*, and *buphthalmia*, and in all cases, in fine, where the eye was the seat of too great an accumulation, either of its natural humors or of any abnormal fluid whatever.

A. *Onyx*.—When the small purulent collections, which are met with sometimes in the substance of the cornea, have obstinately resisted antiphlogistic, emollient and discutient remedies, &c., nothing appears more rational than to open them. The operation, moreover, is so simple that it is scarcely necessary to describe it. The surgeon depresses the lower lid; causes the other to be raised up by an assistant; seizes with the right hand for the left eye, and with the left hand for the right eye, a common lancet, divides the layers of the cornea, which separate the onyx from the exterior, and repeats this puncture as many times as there are distinct abscesses in front of the eye. A cataract needle would be full as good as a lancet, and it is readily understood that we might if necessary make use, with the same advantage, of any sharp-edged pointed instrument whatever. Unless the transparency of the cornea should be irredeemably lost, the instrument ought to be directed as far from the centre of the organ as the disease will possibly permit. In the cases under consideration, surgeons of the present day do not approve either of puncture or incision. It aggravates, they say, or reproduces the inflammation, leaves among its consequences ineffaceable cicatrices, and may hasten, or even produce the suppuration of the eye. Moreover, the matter which forms the onyx, being almost always adherent to the lamellæ of the cornea, is rarely sufficiently fluid to enable a simple incision to allow of its escape. Finally this pus, which never constitutes any other than quite thin layers, spontaneously disappears as soon as the ophthalmia which produced it has subsided or is subdued. While adopting a portion of these reason-

ings, which already have been contested by Woolhouse, Mauchart, &c., I nevertheless consider the operation useful, when, as an exception, the pus constitutes a legitimate abscess. The facts that science possesses, and the last memoir of M. Gierl in particular, appear to me to demonstrate that puncture of the eye under such circumstances, presents unquestionable advantages, and that the moderns have exaggerated its dangers.

**B. *Hydrophthalia*.**—Hydrophthalia, whether accompanied or not by liquefaction of the vitreous body, whether there be or be not blood or pus effused into the humors, possesses in puncture of the eye a last resource, which at the present day, perhaps, has not been had recourse to sufficiently often. It would be doubtless imprudent to commence the treatment with this; but when the proper general or topical medications have proved unsuccessful, and that the difficulties which continue are manifestly owing to an unnatural distension of the globe of the eye, I see nothing more rational than the paracentesis of this organ. By putting a period to the compression of the retina, the iris, and of the ciliary circle, processes, vessels, and nerves, it moderates the most violent pains, and appears to me capable of preventing the most serious disturbances, and to constitute a means, if not curative, at least palliative, and one of the most valuable auxiliary remedies.

I. Paracentesis of the eye, which has been practised in Japan and China for centuries, and performed by Tuberville and Woolhouse, can scarcely be said to have been formally proposed for hydrophthalia before the time of Valentini, (*Coll. Acad.*, partie étrang., t. VII., p. 434,) Nuck, (*Journ. de Simmons*, t. I., p. 282,) and Mauchart. In the beginning it was performed by a small trochar, which Woolhouse recommends should be plunged through the sclerotica, while Nuck directed it upon the centre of the cornea itself. At present, puncture, properly so called, has been generally abandoned. Incision in almost every case is advantageously substituted for it, except that some recommend opening into the anterior chamber, while others, as M. Basedou for example, advise the posterior chamber. Bidloo made use of a bird-beaked lancet, directed upon the lower part of the cornea. Meckren used a large triangular needle expressly made for this purpose. At the present day we more especially employ the cataract keratotome. Saint-Yves made a transverse incision in the transparent cornea. Louis proscribes too large an opening, while Heister recommends that we should incise the sclerotica. Finally, there are those who recommend a puncture first, and who afterwards enlarge the small wound by means of scissors or any other cutting instrument. But in truth, we have in reality only to choose between the process of Bidloo or rather of Galen, and that of Maistrejan and Heister. None of the others in fact attain the object better, and most of them are infinitely more complicated or much more dangerous. The species of cataract needle devised for this purpose by M. Adelmann, who has shown it to me, and which has a groove upon one of its sides, would however possess the advantage of allowing of the escape of the liquid, while at the same time it reduces the operation to a simple puncture. The incision of the sclerotica, whether outwardly or below, and parallel to the fibres of this tunic, con-

stitutes in reality a puncture of little importance, and should have the preference if the aqueous humor could always escape through it. Unfortunately this is not the case. To derive any advantage from it in simple hydrophthalmia, it would evidently become necessary to divide through the *sclerotica* transversely at less than two lines from the ciliary circle, and under this point of view the section of the cornea is certainly a less serious operation. It is only then in cases of liquefaction of the vitreous body, and which are distinguished from ordinary hydropsy by the projection which the iris forms in front, that the operation by the method of Heister could possess some advantage. Moreover it is of little importance in such cases, whether we follow one process or another, inasmuch as the eye is usually lost beyond redemption.

II. *Operative process.*—After having arranged the patient and assistants, in the same manner as for extraction of a cataract; and after having properly separated the eyelids apart, and fixed the eye, the surgeon makes with the point of a lancet, a bistoury, Adelman's needle, or a keratotome, held like a writing pen, an incision of from two to three lines in length, and at the lower or outer part of the cornea, as far as possible in fact from the pupil, and in such manner as not to wound the iris. It is unnecessary then to make any pressure on the globe of the eye. The aqueous humor immediately runs out; and an evident relief is generally the immediate consequence. So long as any hope remains of preserving the organ intact, it would be dangerous to do anything to prevent the wound from cicatrizing. We should dress in the same manner as after the operation for cataract, and should a new accumulation of the liquid seem to render it necessary, repeat this puncture at the expiration of a certain number of days, after the manner of M. Basedow, who gives four successful examples of it, and as I myself have frequently done. No one moreover, at the present day, would recommend that we should imitate Nuck and certain surgeons of the last century, by placing a piece of sheet lead between the eyelids, in order to be enabled to compress the eye from before backwards, so as to make it gradually re-enter into the orbit. A practice like this, which moreover is unworthy of discussion, could not have been adopted but by those who have confounded exophthalmia, buphthalmia, and proptosis, with legitimate hydrophthalmia. Should any point on the tunics of the eye be obviously more altered, prominent or attenuated than others, there is no doubt that this point should be preferred for the paracentesis, and that we should make it a place of necessity. When buphthalmia and the projection of the eye depend upon hydropsy or a dilatation of the *sclerotica*, it is then hydrophthalmia also that we have to contend with, and the puncture is indicated, as in the preceding cases. On the contrary, it could have no object, and must aggravate the condition of the patient, when the disease is owing to the development of some tumor, or to the existence of some organic lesion in the orbit.

C. *Hypopyon.*—Galen appears to have been the first who proposed paracentesis for hypopyon. Nevertheless he did not have recourse to it until after having unsuccessfully made trial of succussion (succussion), so much lauded by Justus, and which Heister and Mauchart

have since thought not unworthy of reviving. According to this author, we open into the lower part of the cornea, a little in front of its union with the sclerotica, and the pus soon escapes to the outside. Aetius recommends that we should perform it with the needle at some point upon the membranes which is not inflamed.

Guy de Chauliac, Benedetti, Paré, and Dionis have adopted the precepts of Galen with success, and despite the efforts of Nuck, Woolhouse and a great number of others, who like the Arabs recommended that we should confine ourselves to one puncture to enable us to suck out the effused matter, and who even went so far as to advise leaving the canula of the trochar in place, and afterwards making use of it for throwing injections into the interior of the eye; modern practitioners also restrict themselves to a pure and simple incision, when they decide upon treating hypopyon by paracentesis. It would be in fact the *best process* to follow under such circumstances were the slightest operation then necessary, and if M. Gierl is to be believed, (*Journ. de Simmons*, t. I., p. 278;) but the small quantity of pus which forms the hypopyon very readily disappears of itself when the ophthalmia ceases; the way to augment its secretion and produce opacity of the cornea, is to open into the anterior chamber with any instrument whatever. Chronic purulent deposits, the only ones perhaps which paracentesis would not aggravate, are constituted of a matter too adherent either to the iris or the cornea, to enable us to evacuate them by means of an incision of a few lines in extent; we must place our reliance in fact upon general treatment, resolvent collyria, and an effort to put a term to such an affection, so long as it does not exceed the limits that belong to a true hypopyon, and so long as we have any hope of preserving the visual function. For all these reasons I am of opinion, with Boyer and Dupuytren, that puncture of the eye, either with a trochar or lancet, is but rarely applicable to abscesses in the anterior chamber, unless like Lehoc we should employ it with the view of renewing the aqueous humor, and at the same time for evacuating the purulent matter.

*D. Empyesis.*—In abscess of the posterior chamber, that is to say, in empyesis or empyema of the eye, it would appear at first view that all the world would concur in the necessity of having recourse to paracentesis. It would however be an error to suppose so. Though many persons have recommended it; and in fact almost all the oculists of the last century frequently made use of it, it can nevertheless be then but a feeble resource. By it we evacuate but in a very imperfect manner the morbid collection. As it soon shuts up, the accidents which belong to it are remedied but temporarily. As soon as the eye is implicated it is irrecoverably lost, and there is no use in incising it any more. We ought to excise a sufficiently large portion of it to evacuate it completely and bring about atrophy. The seton employed in China and Japan, and which had already been eulogized by Woolhouse as a substitute for puncture, and revived by Ford, (*Southern Med. and Surg. Journ.*, June, 1838; *Gaz. Méd.*, 1838, p. 617,) is a barbarous remedy, and unworthy of any criticism.

*E. Practice of the author.*—I have however found that in all these cases repeated punctures on some *region of the sclerotica which remained intact*, by means of the point of a lancet, possessed

a great deal of efficacy. So long as the eye is distended and painful, whether there be *hypopyon*, *empyema*, *hydrophthalmia*, or *ophthalmitis*, I have found nothing better than this practice. I choose the point of the sclerotica which is most visible and projecting, and plunge in the lancet there perpendicularly and parallel to the fibres of this coat. The relief is prompt and the operation may be repeated the day after.

### § VI.—*Excision of the Eye.*

*Staphyloma* of the cornea, *empyema*, *hypopyon*, and *hydrophthalmia*, are almost the only diseases which sometimes require excision of the anterior part of the eye, or for which we may properly have recourse to this operation. Its object is to evacuate the organ, to bring about its atrophy, and to transform it into a simple stump, which may be adapted to the support of an artificial eye. It is therefore a dernier resource, which is not allowable except where all others have failed, and only in cases where it has satisfactorily been demonstrated that the sight cannot be preserved or re-established. In *hypopyon*, *empyema*, and *hydrophthalmia*, for example. it is not to be resorted to until after incision or puncture, unless the insufficiency of these last methods should have been previously ascertained. M. Dugas, (*Ibid.*) in a case of *hemophthalmia*, did not decide upon it until after having lost every hope of preserving the eye. The most ancient authors had already made use of it in *prolapsus* (*procidence*) of the cornea. Galen mentions it as a common method. Aetius recommends that we should associate it with the ligature; and that before removing the *staphyloma*, we should pass two threads through its base crosswise. The ligature that Paul of Egina and others proposed to apply either circular, crucial, or transverse, the taxis and compression proposed by Manget, and the crucial incision of Woolhouse, are now no longer in use, and all surgeons at the present day adopt the advice of Paré or of Louis when they wish to obtain a radical cure of *staphyloma* of the cornea, that is to say, they perform pure and simple excision.

A. *Operative process.*—Whether it be for one disease or another, we must, as soon as we decide upon not removing the entire organ, confine ourselves to the excision of its apex. Cancerous affections alone would constitute an exception to this rule, did they ever allow of a simple excision. In penetrating beyond the iris, up to the middle of the posterior chamber, we should incur the risk of seeing the muscles retract the rest of the sclerotica and the optic nerve to the bottom of the orbit, and of having no stump to the eye after the cure. On the other hand, if we should confine ourselves to a small opening, the humors contained in the chambers would only partially flow out, and the wound might cicatrize too soon, and leave only in its place a depression which would be as great a deformity as the *staphyloma* itself. We should avoid these two extremes by removing almost the entire cornea and without going any farther. Then we are sure that the vitreous humor will finally escape or be dissolved, that a new accumulation of humor will not take place to such extent as to produce a painful distension in the posterior chamber, and that after cicatrization, the muscles will be enabled to impart to the remains of the or-

gan the greater part of the movements which it executed in its natural state, and transmit them to the artificial eye. Nothing is easier than an operation of this kind. The crucial incision with excision of the four flaps, as Richter recommends, is altogether useless. The patient being properly arranged and secured, we divide the lower half of the cornea with Daviel's instrument, the point of a lancet, or any bistoury or keratome, in the same way as for extraction of the crystalline. The flap is immediately seized with a good pair of forceps, and detached in the remainder of its circumference, by means of a very sharp pair of scissors or of a bistoury directed from below upwards. An erigne plunged into the middle of the segment to be removed would render its excision still more prompt and certain in intractable subjects or in those in whom it might be difficult to steady the eye. This process, more simple than that of Terras, who passes a thread through the tumor in order to exsect it more readily afterwards, would enable us in fact to remove as rapidly as possible, and with a single stroke of the instrument, the totality of the cornea or staphyloma, by directing upon its base a good bistoury, which should be made to act either from above downwards or below upwards. The guillotine of Guérin, extolled by Demours, would not be more convenient, and has no claim to a preference.

I. *Consequences.*—There is generally developed after this excision a sufficiently active inflammation in all the parts contained in the orbit, together with fever and cephalalgia, and sometimes even symptoms much more serious. In general, however, at the end of from eight to fifteen days, the swelling which it has occasioned begins to diminish; the suppuration, at first abundant, soon dries up, and towards the end of the month, or a little sooner or a little later, we are enabled to adjust the artificial eye. As it is not an operation without danger, we ought to make this known to those who demand it for simple deformities, and ought not to perform it under such circumstances, except at their solicitation, as in cases, for example, of ancient staphyloma, unaccompanied with pain. When, on the contrary, the disease which it is designed to remedy is dangerous in itself, as empyema, hydrophthalmia, &c., we must not hesitate. Before such affections as these, every apprehension should be banished. Punctures of the sclerotica, I should think, would diminish the inflammatory reaction and ought to be had recourse to.

## § VII.—*Extirpation of the eye.*

Though extirpation of the eye was not clearly described until near the close of the sixteenth century, there is however every reason to believe the ancients had had recourse to it quite frequently. There were two principal classes of conditions in which it was made use of: 1st, for proptosis, or the fall of the eye; 2d, for deep-seated diseases and degenerations of this organ.

A. *Proptosis—Exorbitism—Fall of the eye.*—J. Lange, who wrote in 1555, boasts of having caused the re-entrance into the orbit of an eye which certain surgeons had proposed to extirpate. Donat, at a little later period, in 1588, endeavored to demonstrate the inutility of this operation, and maintained that compression, aided by the judi-

cious employment of internal remedies, always triumphed over those diseases which seem to require it; which proves at least that for a length of time it has been known to practitioners. Bartisch, therefore, who only published his work in the year 1583, has no claim to the merit of the invention, and has only drawn attention to a serious operation. and one which had already been performed, but the execution of which he rendered more easy.

Some authors, as Covillard, Lamswerde, and Spigel, also profess to have cured without an operation, patients in whom the eye violently protruded from the orbit and hung upon the cheek. A. Seigneur stated to Guillemeau, (*Œuvres Chir.*, p. 743, edit. 1612,) that his surgeon seizing an eye which had fallen to the ground, successfully replaced it in the orbit. An eye which had issued from the orbit in consequence of inflammation, was replaced by Loyseau, (*Obs. de Méd. et de Chir.*, p. 46; *Corps de Méd.*) The eye of Captain Naldi, according to Rhodius, (Bonet, t. III., p. 50,) which had been driven from the orbit by a blow given by a Turk, miraculously returned to its place by means of a large cupping glass upon the occiput. In a young infant, the eye which had inflamed and become as large as an egg, and escaped from the orbit, returned there by means of topical applications administered by F. Plater, (Bonet, t. III., part 2nde, p. 50.) Verduc (*Pathol. Chir.*, t. II., p. 44–47, in 12,) does not admit the fact of Covillard, but Lemaire, (*Eaux de Plomb.*, &c., p. 59,) saw the same thing in a hemiplegic at Plombières. Salmuth, (Cent. 2, hist. 42, état d'Ettmuller, *Prat. Méd.*, t. II., p. 401. French trans.) speaks of an epileptic, in whom the eye during a paroxysm protruded to the size of the fist, and returned after this had ceased. Verduc, (*Pathol. de Chir.*, t. II., p. 244, in 12, 1719,) moreover, admits to have seen a young painter, whose eye descended to the middle of the cheek, and which in less than the space of an hour, descended from, and returned to the orbit more than six times. In a patient of C. White's, (*Cases in Surgery*, 1770; *Gaz. Salut.* 1771, No. 27, p. 3,) the eye, luxated upwards by the contraction of its levator muscles, was relieved by the taxis: a wound made by a fragment of pipe-stem which had entered at the bottom of the orbit, was the cause of the difficulty. In a case of protrusion of both eyes, says Rossi, (*Elem. de Méd. Oper.*, t. I., p. 203,) which took place after violent vomitings, I found after the remedies which I had employed to give greater strength to the muscles of the eye in restraining the globes, that the use of electricity and camphorated vapor produced a marvellous effect. M. Champion has known an old lady who was affected with strabismus in the left eye, and in whom this infirmity succeeded after the reduction of the eye, which had been driven from the orbit out upon the cheek in consequence of a blow received upon the temple. I frequently meet, says the same practitioner, with a retired officer, who declares that he had a protrusion of the right eye which it had been proposed at the time to excise, but which was perfectly reduced and is now in possession of all its functions. The accident was said to have been produced by a ball which had traversed the left orbit, and which had come out at the inner angle of the right one. Maitrejan has long since shown the impossibility of such a result taken literally; but Louis has very

justly remarked, that in divesting the assertions of observers of every thing hyperbolical that they possess, we find in them the proof that the optic nerve and the muscles which surround it may undergo a considerable degree of elongation without necessitating the extirpation of the eye. We have, moreover, numerous examples of this elongation effected in a gradual manner, in cases of exostoses, and tumors of every description in the orbit, nasal fossæ, maxillary sinus, &c. If the eye really hung down on the outside, in consequence of a traumatic lesion, we should then, instead of attempting to replace or preserve it, complete its separation and remove it immediately. In such cases there is no process to be given. A single cut of the scissors or bistoury sometimes suffices, and the conduct of the surgeon must necessarily be regulated according to the accidents which exact so severe a remedy. When on the contrary the eye has only been expelled gradually from the orbit, whether entirely or partially, or whether it be or be not in itself disorganized, we should do wrong to attempt its extirpation.

It is not to the eye itself that the resources of surgery are to be addressed. Let the operator destroy, or cause the disappearance of the principal disease if he can, and the displaced organs will soon resume their normal situation. St. Yves cured a severe exophthalmia, by effecting the resolution of scirrhusities which had been formed in the bottom of the orbit. Brossaut, who is mentioned by Louis, has seen the vision re-established, and the eye re-enter into its cavity, when the exostosis of the ethmoid which had caused its expulsion had been destroyed; Guérin of Bordeaux, and Dupuytren, have brought about the same result by removing the various tumors and cysts, of which the tissues which surround the eye are very frequently the seat. Extirpation of the eye therefore is not called for in buphthalmia nor exophthalmia, whatever may be their cause, nor in hydrophthalmia, empyesis, or staphyloma.

*B. Cancers of the Eye and the Orbit.*—Cancerous affections only allow of our undertaking extirpation of an eye which has not been displaced. Even when their existence has been well established, the question still remains whether the operation should be attempted. Those who go for the affirmative, with Desault, &c., argue principally that cancer of the eye is much more frequently observed in children than in adults, and that in the younger period of life its reproduction is much less to be apprehended than after puberty. Others appeal to the researches of M. Wardrop, which show that the disease is almost always constituted of *fungus hematodes*, a melange of encephaloid, erectile, colloid or melanotic tissue, or one of those substances only. But since there is no variety of cancer which repululates, either in the same place or elsewhere, with more obstinacy than this, they maintain that it would be inflicting unnecessary suffering upon the patient, and that we ought to limit ourselves to simple palliatives. What analogy and reasoning had foreshown to them, experience has but too often demonstrated. Whatever, in fact, some authors may have said on this subject, the labors of the ancients, like those of the moderns, sufficiently prove that the ablation of cancer of the eye is not less liable to a return of the disease than that of any other part. I would not, however, therefore conclude that we ought to

remain inactive. Far from that, I think we ought to exert ourselves to operate before the viscera have had time to become invaded by the morbid germs, and as soon as the nature of the disease appears no longer doubtful, and so often as it shall appear to be practicable to remove it entire. All this, however, belongs to the general question, whether it is advisable or not to operate for cancer.

1. *Operative process.*—*a. Process of Bartisch.*—The extirpation of the eye, much more frightful than difficult, more formidable by its consequences than its immediate dangers or the difficulty of its execution, may be performed by quite a number of different modes. We find no details on this point in authors before the time of Bartisch, who, in order to excise the diseased parts, found no other instrument necessary than a species of spoon with cutting edges, like that used by shoemakers. Though no person at the present day would venture to recommend so crude an instrument, it is incorrect to say that it exposes to the risk of fracturing the bones, and that it renders the operation much more difficult than with any other knife. Its dimensions, it is true, do not allow of our carrying it as far as the extreme depth of the orbit, but I do not find that it is often required to go to this distance. To be just, therefore, we should limit ourselves to its rejection as useless, or possessing but little advantage. The excavated scissors of Delpech, (*Dict. des Sc. Méd.*, t. VII., p. 528,) and the concave scalpel of Mothe, (*Journ. Gén. de Méd.*, t. XLVIII., pp. 121—136,) are scarcely better.

*b. F. de Hilden*, who had occasion to extirpate an eye in 1596, proposed at first to embrace the projecting part by means of a string purse. After having censured the instruments of Bartisch, (Cent. 6, obs. 1,—Bonet, *Corps de Méd.*, p. 389,) he speaks of the simple strangulation extolled by C. H. Chapuis. Detaching the tumor from the eyelids by the cuts of the bistoury, he employed for the section of the muscles and optic nerve a sort of scalpel with two cutting edges, curved flatwise, and truncated at its point. In this process we already recognize the principles of a more enlightened surgery, and the practitioner mentioned by Bartholin (Louis, *Dict. de Chir.*, t. II., p. 124,) is justly censurable for not having profited by it about fifty years subsequently, and for not having recoiled at the idea of tearing out the eye by means of a pair of hooks. The instrument of Hilden, though more ingenious, has nevertheless met with the same fate as that of Bartisch. If Job-a-Meckren succeeded with the spoon of the oculist of Dresden, and Muys and Leclerc with the knife of Hilden, Lavauguyon maintained that a good lancet fixed on its handle would always suffice, and might be substituted for them. St. Yves, for every step of the operation, found nothing else required than a thread to secure the cancerous mass, and a cutting instrument, which he does not designate. Nor do the observations of Bidloo make any mention of a particular knife, except it be a long bistoury bent to an angle, near its handle, and which is also praised by V. D. Maas.

*c.* It was Heister who showed, by sufficiently good reasoning, that an erigne or forceps, and the ordinary bistoury, which Hoin of Dijon had already found to answer in 1737, are sufficient for this operation.

*d.* Things were in this state when Louis undertook to systematize the ideas of surgeons on the extirpation of the eye. When the tumor

no longer holds on except by the root of the recti muscles and of the optic nerve, we must, says this surgeon, make use of a pair of scissors curved flatwise; pass them to the bottom of the orbit, then divide the musculo-nervous pedicle, and at the same time act with them as with a spoon to bring the whole forward.

*e. Desault*, who, in the first years of his practice, had adopted the process of Louis, ultimately abandoned the scissors as useless, and confined himself to the simple bistoury, which in fact is better than the curved bistoury of B. Bell. Sabatier, Boyer, Dupuytren, and all the operators of the present day, conform themselves to the recommendations of Louis or of Desault almost indifferently. With the curved scissors we run no risk of penetrating into the cranium or into the zygomatic fossa. Their concavity accomodates itself better to the form of the tumor, whose pedicle also they would seem to embrace with more security. But with a bistoury it is not necessary to change the instrument, from the commencement to the end. The section of the soft parts is more neat, and all that is required is to incline it in one direction while the eye is drawn in another, in order to reach with facility the root of this last. We should have to be very unfortunate or very inexpert to perforate with its point into the optic foramen or maxillary and sphenoidal fissures. It is therefore here also, as we have so often already said, an affair of choice or circumstances, much more than of necessity.

*First stage.*—The patient may, if necessary, be kept seated upon a chair, but it is better to operate upon him in bed, taking care to raise up his head considerably. The surgeon being placed upon the side of the affected eye, acts differently according as the surrounding parts are or are not invaded by the cancer. In the first case he adopts the precept of Guérin, and makes two semilunar incisions, which enable him to circumscribe the base of the orbit and to detach the eyelids from it in order to remove them with the rest of the disease. In the second case he is to do all in his power to preserve the connections of the eye. If they have contracted adhesions without having undergone an actual disorganization, he dissects each eyelid on its inner surface and reverses it outwardly. When the globe of the eye is found to be free behind, all that is necessary is to prolong with one cut of the bistoury the outer palpebral angle to the extent of about an inch towards the temple, as Acrel, and not Desault, appears to have been the first to have formally recommended. In all cases an assistant secures the head of the patient, and keeps himself prepared to follow and to favor all the movements of the operator. This last secures the projecting part of the tumor with his hand if he can, after the manner of Desault. Otherwise he makes use of a simple erigne or double hook, an erigne forceps like that of Museux, or the string purse of F. de Hilden, or better still, as St. Yves recommends, (or a strong simple ligature or ribbon cross-wise,) after the manner of Chabrol, (*Gaz. Salut.*, 1782, No. 49, p. 4.) passed by means of a needle through the degenerated mass.

*Second stage.*—The operator takes the bistoury in his right hand, holds it as a writing pen, and directs its point to the great angle of the eye; plunges it in while grazing the ethmoid bone as far as to the neighborhood of the optic foramen, makes it pass round flatwise the entire

lower semicircumference of the orbit; divides the attachment of the small oblique muscle, the oculo-palpebral groove of the conjunctiva, and some adipo-cellular filaments; then brings it back into the inner or nasal extremity of the wound; directs its cutting edge upwards and then outwards; divides the great oblique muscle, and endeavors to remove at the same time the lachrymal gland, when, by passing around the orbital vault, he arrives near the temple and finds himself at the point of uniting the two wounds by their outer extremity.

*Third stage.*—The eye now holds no longer than by means of a pedicle formed by the four recti muscles and the optic nerve. If, in order to divide this pedicle, we prefer the scissors, the operator glides them upon the inner rather than the outer side, with their concavity turned towards the tumor to as great depth as possible, and with a single cut completes the separation of the cancer. If any bridges still retain it, they are to be rapidly divided in the same manner, while with the other hand we make the proper tractions. If, in place of the scissors, the surgeon has recourse to the bistoury, he directs this also, by preference, upon the inner side. In this direction the orbital wall being almost straight, it is easy, by inclining the point of the instrument outward, to cross and divide the musculo-nervous pedicle. I am ready, however, to avow that with the bistoury, as well as with the scissors, it would not be attended with much more difficulty to attain the same object by following the temporal wall of the orbit. It was, in fact, here that Desault usually entered it by choice, remarking that this route was the shortest and most convenient.

An object more worthy of attention, is that we are more certain by this mode to avoid falling upon the maxillary and sphenoidal fissures. Whether the lachrymal gland be cancerous or not, we must when we have missed it, seize it immediately after with an erigne or forceps and extract it. The secretion of tears being no longer of any use must necessarily be injurious. It must be by inadvertence that some have thought proper to sustain the contrary opinion. This gland when left in the orbit after the removal of the eye, kept up a copious discharge of tears with accidents, which obliged M. Nelle (*Encyclogr. des Sciences Méd.*, 1838, p. 250) to extirpate it six months subsequently. We may moreover, by directing the forefinger into the orbit, accurately ascertain the condition of the parts that remain; and if there are any of them which are not sound, we should endeavor to reach them before we have finished the operation, and remove or destroy them, either by means of the bistoury, the scissors, or even the rasp.

II. *Dressing.*—No artery of any size can have been wounded. All those which are divided come from the ophthalmic; and their ligature is unnecessary, even though the blood should flow in abundance. Small balls of lint sprinkled or not with colophane and more or less pressed upon, would be sufficient to arrest it. In ordinary cases we fill up with lint the void which has been left, but moderately and as if for the purpose of supporting the posterior surface of the eyelids. The sponge, which has been proposed by some practitioners in lieu of this substance, would have the disadvantage of

irritating the tissues by becoming swollen in the middle of a solid cavity. The small bag filled with emollient cataplasms also, as recommended by M. Travers, and which is placed over all the other dressing in order to prevent the slightest degree of compression, does not appear to me to present any real advantages. At the expiration of four or five days the suppuration is established. The lint is removed without any effort. Nor is there any objection if we wish to make the removal of the first dressing still more simple, in covering the bottom of the wound with a fine linen besmeared with cerate and perforated with holes, and which serves as a sac to the compresses, and when the eyelids have been removed may be easily reversed upon the contour of the orbit. A soft plumasseau, and which is sufficiently large to support in front the more deep-seated portions of the dressing, together with a long compress placed obliquely, and the monocle bandage, complete the dressing, which the least skillful surgeon moreover will know how to modify in a proper manner, should circumstances make it necessary. After its first removal, which is from the third to the sixth day, the dressing has no longer any thing particular in it. The wound being washed with tepid water and gently wiped out, should be supplied each time with a small quantity of dry lint. The eyelids being gently raised up and protected by small bandelettes besmeared with cerate, are finally covered with a soft plumasseau and a compress; the whole is supported by the monocle and a few turns of bandage. The cure is usually effected between the third and tenth week.

III. *Remarks.*—Though the preservation of the eyelids would render the deformity less repulsive, it would nevertheless be preferable to sacrifice them rather than not to destroy the remotest vestiges of the disease. The incision at the external angle renders the remainder of the operation more easy, and does not involve any particular accident. One point of suture or a simple adhesive strap would moreover effect its reunion without any exertion or inconvenience. If we should commence by the superior incision, the blood which oozes out would necessarily create a slight degree of embarrassment for that below. The eyelids having their fixed point upon the inside, we manipulate with more security from the nose towards the temple than from the outer to the internal angle. When the globe of the eye alone is affected, as it is attached in front only by the fold of the conjunctiva and the oblique muscles, it is not necessary to carry the instrument over an inch in depth. On the contrary, when adhesions are established between the soft parts and the bones, we must go as deep as the bottom of the orbit. In such cases the spoon-knife of Bartisch, the scalpel of Hilden, and the bistoury of Bidloo, would incur the risk of fractures, which it is always advisable to avoid. It is under such circumstances also that any sharp-pointed instrument whatever, if directed without precaution, might fracture the frontal bone and penetrate into the brain, should we, in order to reach with more certainty the levator muscle or lachrymal gland, elevate its point too much; or it might arrive into the maxillary sinus and divide the suborbital nerve or vessels, if we should incline it too much in the opposite direction; or penetrate into the nasal fossæ inwardly, or into the zygomatic or pterygo-max-

illary fossa posteriorly, and wound the second branch of the fifth pair of nerves (nerf trijumeau) or the internal maxillary artery; or in fact penetrate into the cranium through the sphenoidal fissure, and wound the middle lobe of the cerebrum. If the bistoury, however, should not graze the bones, we should incur the risk of not removing all the cancer, and of being obliged to operate again afterwards. The lachrymal gland in particular being almost entirely concealed behind the external orbital process, cannot be extracted with the eye except with a good deal of difficulty.

The rasp recommended by Bichat, or the chemical caustics, would be less dangerous than the *actual cautery*, at least on the side of the orbital vault, should it become indispensable to go beyond the soft parts. In fact, the proximity of the brain would, under such circumstances, render the application of the iron extremely dangerous. Should the fungus have commenced at the exterior of the eye, there would be reason to apprehend that there were branches of it in the direction of the temple, sinus maxillary, the nose, &c. M. Simonin (*Decade Chir.*, p. 21, 1838,) having extirpated the eye, was obliged to resort to tamponing; and his patient died. The roof of the orbit was perforated, and blood was found under the dura mater. Being desirous of arresting the blood and of destroying some remains of cerebroid tissue in the temporal fossa and maxillary sinus, I applied there an olive-shaped cautery, avoiding with care the vault of the orbit. The patient died on the third day, and we found an extravasation of blood in the corresponding lobe of the brain. Was it the operation which was the cause of this apoplexy, or was it not only a mere coincidence? Though we may be in the habit of employing the same hand for the first and second incision, it nevertheless appears to be more convenient for the right eye, for example, to execute that of below with the right hand, and that of above with the left one, unless we wish to make one of them from the temple to the nose. We divide the levator muscle, because otherwise it would constantly tend to draw the upper eyelid inwards after the cure, and might in this manner still further increase the deformity. I have forgotten to say that Dupuytren began with the upper incision, and that he terminates by detaching the organ from the summit to the base of the orbit.

### § VIII.—*Artificial Eyes.*

Nothing, doubtless, would be more desirable than to be enabled to make use of an enamel eye, when the disease has permitted us to preserve the integrity of its movable coverings; but we must not flatter ourselves too much on this point. The orbit, like all other natural cavities, when once emptied and void shrinks upon itself. Its walls approximate gradually from the bottom to the exterior. Its circumference diminishes and becomes depressed in such manner that at the expiration of a certain time, it is found to be almost completely effaced by this contraction, and also by the development of a fibro-cartilaginous substance. The eyelids being obliged to conform themselves to this retraction, contract adhesions on their posterior surface, are deformed, and become in most cases incapable of adapt-

ing themselves to the artificial organ that we wish to place behind them. If the patient, therefore, is desirous of concealing his mutilation, we must be prepared whether the eyelids have been destroyed or not, to be under the necessity of employing only spectacles that have been artistically arranged, or with a colored plate, which is to be fixed in front of the obliterated cavity. The ancients, as it appears, devoted more attention to these matters than ourselves. We find that they had two species of artificial eyes, one to be inserted as at the present day behind the eyelids; the others, which were still used in the time of Paré, who is said to have been the first who spoke of them, and which were a sort of convex plates upon which the anterior part of the eye and its coverings were painted in wax colors, were to be kept in place by means of a spring. Formerly the first were made of gold or silver: at the present day the enamel is properly preferred. In these eyes everything is to be represented, the cornea, the iris, pupil, the sclerotica and its vessels. To apply them, one of them was held by the extremities of its longest diameter with the forefinger and the thumb, in order to pass its upper border under the frontal eyelid, while the eyelid was gently raised up with the other hand. This being done, it enters so to speak of itself, as soon as the other eyelid is depressed. In order to remove it when going to bed at night, the patient glides under it the head of a pin, and depresses the lower eyelid while drawing the lid forward. Being deposited in a glass of water during the night, this eye should be carefully cleansed every morning before being replaced. It is unnecessary to remark that its dimensions ought to be in relation with the orbit of different individuals, and that it is important that another eye should be substituted as soon as the first begins to change. When the enamel eye has been properly constructed, and that the two posterior thirds of the natural eye remain to form a stump, the resemblance sometimes is so striking as to produce a complete illusion. In the contrary case, as it is not susceptible of movement, it remains fixed in the centre of the orbit, and unfortunately cannot be concealed in those who are obliged to wear it.

[M. Morant, of Mettréy (*Arch. Gén. de Méd.*, June, 1844, 4e sér., t. V.) having found cases of epidemic ophthalmia accompanied in the beginning with coryza, was thereby induced to try repeated *cauterizations* to the *mucous membrane of the nasal fossæ*, which proved in many instances an effectual remedy.]

*Encysted spheroidal liquid tumors in the anterior chamber of the eye*, with the capsule and contained liquid more or less transparent, and the whole adherent to the iris, have been noticed in a few instances, (see a case by J. Dalrymple, *London Lancet*, August, 1844, and Tywell on *Diseases of the Eye*—also *Archiv. Gén.*, Paris, Mars, 1845,) and are cured either by puncture or by dissecting out the cyst.

*Abrasion of the cornea for cure of Opacity*.—M. Malgaigne exhibited to the Royal Academy of Sciences of Paris, April 28, 1845, (see *Arch. Gén.*, June, 1845, p. 236.) a young girl in whom an opacity of the cornea was completely removed, and transparency restored, by an abrasion of one half the thickness of this coat two years before. T.]

## CHAPTER III.

## DISEASES OF THE MOUTH.

## ARTICLE I.—LIPS.

§ I.—*Harelip*.

The labial fissure known under the name of harelip, is either acquired or congenital. That which takes place after birth is noticed almost as frequently upon one lip as upon the other; the congenital, on the contrary, up to the present time has rarely been observed except on the upper lip. The facts cited by Meckel and Nicati, who profess to have seen it on the lower lip, are truly exceptions. Since Louis maintained that the harelip is not accompanied with any loss of substance, Blumenbach, Tenon, Béclard, Meckel, &c., have endeavored to explain its formation according to certain laws of the organism, and to show that its different modifications were the result of an arrest of development, (*arrêt de développement*.) Three portions, according to some, constitute the upper lip in the beginning, a median and two lateral. There are even four, according to others, who maintain that the middle part is also divided primitively into two. According to this hypothesis simple harelip is owing to one of the embryo fissures of the lip having persisted, and the proof of this, they say, is that it is almost constantly found outside of the median line. When the two lateral parts remain isolated from the middle part the harelip is necessarily double. If the authors of some observations already ancient, and more recently Moscati, were not deceived, and if they have really seen the harelip placed exactly in continuation with the septum of the nose, it could be explained by admitting the non-union of the two halves of the median lobe of the lip. Finally, at the lower lip, where, as in the case of Tronchin, (*Petit, Dissert. sur le bec-de-lièvre*, p. 5, 1826, Strasbourg,) it induces marasmus by the loss of saliva, the congenital harelip must always occupy the median line, because in its formation they say it never has more than two portions. Numerous researches on embryos and the fœtus at every period, induce me to believe that these ideas are the result of erroneous observations or gratuitous suppositions. Harelip is not always without loss of substance, and the lips are no more formed of two, three, or four portions, at three, four, six, or eight weeks, than at three or four months. As soon as we see them begin to point they appear to be entire, like the buccal aperture that they accurately encircle. The contrary happens only by accident. Harelip, like most other monstrosities, has appeared to me to be much more frequently ascribable to some disease than to a defect in its natural evolution. This doctrine, which I endeavored to disseminate since 1825, counts at the present time powerful advocates. I see with pleasure for example, that M. Cruveilhier fully adopts it. If he promulgates it as his own, it is probably because he has not taken notice of what I have said of it in various places in my publications, especially in the first edition of my *Tocology*, and of this present work.

*A. Simple Harelip.*—1. *Analysis of the methods.*—Though harelip is one of the most common deformities of infancy, it has nevertheless attracted but very little attention from the ancients. Celsus, who was the first to mention it, speaks of it however quite obscurely. The Arabs make but slight allusion to it, and every thing goes to show that up to the time of Franco or Paré, its treatment had not been the object of as much attention as it merits. At the present time, however, this is a point of practice which seems to leave nothing to be desired. To effect the cure three indications are to be fulfilled. Its borders are to be abraded, its two sides approximated, and the two lips of the division maintained in perfect contact until they have become agglutinated.

*a. Abrasion.*—It was with the *hot iron* that Abu'l Kasem, as well as Ludovic, effected the *abrasion* of harelip. *Butter of antimony*, or some other chemical caustic, was preferred by Thevenin, and Hunter made use of nitrate of silver. Chopart, yielding in this matter to the advice of Louis, considered that he would succeed better by applying upon the borders of the fissure which he wished to inflame, two strips of *blister plaster*. Such means could not have, and in fact have not produced any but imperfect results, and have properly been abandoned. *Excision* only, which had already been in use in the time of Celsus and Rhazes, is allowable at the present day. In order to effect it, D. Scacchi and Dionis made use of the *ordinary scissors*, and Henckel of *blunt-pointed scissors*, (*ciseaux boutonnés*.)

M. A. Severin and Acrel, on the contrary, gave an exclusive preference to the *bistoury*, which Louis and Percy endeavored to bring into general use; while Roonhuysen, De Horne, Le Dran, and B. Bell, had recourse almost indifferently to the one or to the other of these two instruments. The partisans of the *bistoury* maintain that it produces less pain, gives a neater wound, and one that is less disposed to suppurate; that the scissors cutting much more by a pressing than by a sawing movement, contuse the tissues and make a bevelled wound, or one with a double oblique plane, which is but little favorable to immediate union. Experience has a thousand times demonstrated the slight foundation there is to these objections. Bell being desirous of ascertaining the fact, operated on one side with the scissors, and on the other with the *bistoury*, without apprising any person of it. The patient, first embarrassed in giving an answer, ultimately declared that the pain had been more acute at the side upon which the *bistoury* had been used. The scissors, adopted in preference by Van Horne, (*Introd. Method de la Chir.*, Severin, *Med. Effic.*, S. 28,) Lombard, (*Clin. Chir. relat. aux Planes*, p. 38, 1802,) &c., have the advantage of requiring no point d'appui, and of instantly dividing every thing that we wish to remove. Desault, who earnestly defended them, recommended that they should be very thick, and that the blades should be strongly sloped. Those which are preferred at the present day, and which bear the name of those of A. Dubois, are constructed upon this principle. In order to increase with greater effect the power which is to move them, a great relative length is given to their handle. Their blade, which is short and solid, in this manner cuts with all the precision

desirable. It would be an error, nevertheless, to conclude that the bistoury would not answer. As to the manner of its employment, it has singularly varied. Le Dran, imitating Guillemeau, began by plunging in its point through the lip from the mouth towards the skin, a little above the summit of the division, and afterwards divided perpendicularly from above downwards, or from behind forwards, as far as to the labial border, doing the same afterwards at the opposite side. B. Bell adopted a course directly the converse of this. Placed behind the head of his patient, with the bistoury held as a writing pen, he made his incision set out from the free border of the lip, and extended it from below upwards and from before backwards as far up as above the summit of the abnormal fissure. Enaux, after having destroyed the folds and adhesions which unite the alveolar arch to the lip, glides behind this last a piece of cork, upon which he recommends that the lower angles of the harelip should be supported, in order that the bistoury may thereby be furnished with a point d'appui. In place of the cork, recommended by Enaux, we generally confine ourselves to a piece of pasteboard, or simple playing-card, or portion of soft wood. The forceps, or *morailles*, either of metal, like those of J. Fabricius and Lauth, (Erhmann, *Dissert. sur le bec-de-lièvre*,) or of wood, like those used by M. A. Severin, which served to fix the lip while its exsection was being made, which by the greater breadth of their posterior branch, could replace the piece of pasteboard which the use of the bistoury required, and which also had for their object to aid the approximation of the two abraded borders, and to prevent hemorrhage, have been long since rejected from practice. Heister, Acrel, and B. Bell are, I believe, the last authors who have thought proper to recommend them.

*b. Reunion.*—After the abrasion of its borders, the harelip is found reduced to the condition of a simple wound, and its immediate reunion is to be attempted either by means of suitable bandages or the suture, or by combining those two modes together. Franco, who confined himself to plasters fixed upon the cheeks, and small strips crossed under the nose, in order to make what he called the dry suture, then by a containing bandage; F. Sylvius, who, according to Muys, succeeded with the adhesive plaster alone, also supported by a bandage, and Purmann and G. W. Wedel, who, it is said, were not less fortunate, found in Pibrac, and especially in Louis, a warm defender. According to this author, the bloody suture is not only unnecessary, but also injurious. Unnecessary, because the harelip being unaccompanied with any loss of substance, it is always practicable to effect its approximation by means of the uniting bandage for long wounds; injurious, because its presence is a permanent source of irritation, which cannot fail to bring into action the muscular retraction. Following out this principle, Louis used only a single point of interrupted suture, and to complete the reunion employed a simple band. The ideas of Pibrac, who desired, so to speak, to proscribe the suture from surgery, appeared to find in this operation a judicious application. Valentin, in order to effect a more perfect coaptation, devised a clasp or sort of double flat forceps, capable of embracing the two sides of the wound, and of being approximated at pleasure by means of a transverse piece and screw. Enaux, (*Acad. de Dijon*, 1783, t. II.,

p 220,) in order to avoid the contusion and unequal compression made by the instrument of Valentin, proposed a bandage, the model of which exists in the museum of the faculty of Paris, and which by being attached by as many circular arcs at the top of the nape, at the vertex, and under the lower jaw, presents two pelotes which are intended to push the soft tissues forward, when they are applied upon the cheeks, and which may be reunited in front of the wound by passing a strip from one to the other.

Evers rejects all these modes, and confines himself to two adhesive strips, which he crosses obliquely (*en sautoir*) below the nose. M. Dudan has since invented, with the same object, a new clasp based upon the principle of that of Valentin. For another we are indebted to M. Montain, (*Thérapeut. Méd. Chir.*, &c., 1836, p. 16,) who assures us that he has made use of it with advantage both in children and in adults. Brunazzi (*Gaz. Salut.*, 1792, p. 294, 12 July,) Giraud St. Rome (*Soc. Méd. de Marseilles*, 1811, p. 23,) and M. Kluykens (*Bull. de la Fac. de Méd.*, 1811, p. 184,) have also obtained successful results with the contrivances of their invention. There is no doubt that in this manner we may sometimes cure harelip; but it is incontestable also, that in the majority of cases the reunion is badly and imperfectly made, and that there frequently remains a groove either in front or behind, and at the lowermost part a notch almost as disagreeable as the first disease, while the bloody suture, if properly adjusted, protects us from all these inconveniences. It is also the one which is exclusively used in our time, and the bandages, including that of Terras, (*Lassus, Méd. Operat.*, t. II., p. 388,) are no longer recommended except as accessories.

c. Celsus, who *sewed up* the harelip, does not give sufficient details to enable us to understand what kind of suture was employed in his time. It is probable from what Albucasis says of it, that the glover's suture was the one made use of by the Arabs. Others, as Heuermann, Ollenroth, and W. Dros, for example have recommended the *interrupted* suture, which was also preferred by Lassus, in order not to be obliged to leave inflexible metallic stems in the wound. There is no kind of suture, even the *quilled*, which has not had its partisans, though the *twisted* suture is the one which has been almost always preferred. In order to have a kind of twisted suture, M. Van Onsenort places upon each side of the borders of the wound a narrow ivory plate pierced with three holes; having introduced his threads with an ordinary needle, he knots them on the plate on the left side. M. Mayor (*Gaz. Méd.*, 1838, p. 737,) recommends one or two points of suture attached to (*entraînant*), a roll of lint or cotton, and which are to be fixed upon a similar border. A. Paré, the first author who describes it in exact language, made use of the twisted suture by means of needles furnished with eyes, and which he inserted from one side of the wound to the other, and afterwards fixed by means of turns of thread passed in a figure of 8 round their extremities.

d. Fabricius ab Aquapendente employed flexible *needles*, the extremities of which, after having inserted them, he bent forwards. Those of Roonhuysen were angular or triangular, like those of Paré. He surrounded them with a thread of silk and cut off their point with the cutting pliers. Dionis recommends that they should be of

steel and curved. La Charrière, in place of clipping off their points like Roonhuysen and Dionis, used only a small compress between the skin and their extremities. In order to introduce them without difficulty, notwithstanding their small size, Heister made use of a needle handle, and J. L. Petit, who made them still stronger, and provided each of their two extremities with a head, fabricated them of silver and conducted them by means of a sort of punch. Le Dran preferred that they should be of gold, in order that they might be at the same time very solid, though sufficiently firm, and not oxydizable, and that they should have a flattened point and be provided with a head, to avoid the employment of a needle handle. If gold and silver possess the advantage of not rusting, they also have the inconvenience when we wish to make cutting instruments of them, of not penetrating as easily through the tissues. In consequence of this, Sharp proposed to solder upon his silver needles a spear-shaped steel point. Wedel asserts that ordinary needles are sufficient, and that we should surround them afterwards with a hempen thread. De la Faye maintains that without having recourse to so much preparation, strong long copper pins, in a word, German pins, are preferable to all others. As their point might wound the patient, Mursinna recommends to protect it afterwards by means of a small piece of quill. Le Dran had found it more convenient to make use, for this purpose, of a small ball of wax. Arnemann (Sprengel, t. VII., p. 136), had them hollow, the head and point of which might be removed at pleasure. Those of Desault, which are of silver with a steel point, are made so as to diminish in volume from their cutting extremity to that which is to support the action of the finger, in order that they may be extracted without bringing them back again through the same track that they have entered, and without passing their cutting portion a second time through the flesh. These are the ones which in France at least have been almost universally adopted. We cannot see indeed that there is any objection to them unless it be that ordinary pins, such as are everywhere met with, may notwithstanding be wholly substituted for them, if before inserting them we take the precaution to sharpen their point a little, in order to flatten it by rubbing it against a tile in the apartment, or some stone vase or any hard stone.

e. The *semilunar incisions*, with their concavity forwards, which Celsus made on the inside of the cheeks, and which Guillemeau, Thevenin, and Manget, made on the outside, and the dissection and gashes on the posterior surface of the lip which Franco, (*Traité des Hernies*, &c., p. 460, 1561,) J. Fabricius and D. Scacchi recommended in order to favor the approximation of the borders of harelip are no longer to be mentioned in simple cases, except to expose their absurdity and barbarity. I have mentioned in the chapter on anaplasty under what circumstances they may be useful. But this does not apply to the suggestion of preparing beforehand the parts which are to be approximated. In place of the pincers of Fabricius, &c., V. D. Haar, and after him Arnemann and Knackstedt of Petersburg, have recommended a bandage which, after having been employed for a week or two, is capable of approximating towards the median line the points which it is important for the operator to bring

into contact. It rarely happens, however, that the moderns consider themselves obliged to follow out this indication, inasmuch as they know that an ordinary uniting bandage would perfectly attain the same object. Unless the separation should be extreme, the immediate approximation of the sides of the wound is usually attended with but very little difficulty.

*f.* Surgeons at different epochs, apprehending that in spite of the suture the parts might ultimately retract, have endeavored to find some means of obviating this inconvenience; from whence is derived that multitude of dressings with which the science is overcharged, and that combination of the dry suture or *bandages* with the bloody suture. In this respect Dionis is the one who appears to have given the example. He placed an agglutinating plaster in front of his twisted sutures, and supported the whole by means of a bandage with four tails. La Charrière considered that by means of a circle of steel, which surrounded the head, and by graduated compresses which he placed upon the cheeks, success would be unavoidable. It was for the purpose of replacing his bandage, as modified since in various ways by Quesnay, Heister, Henkel, Koenig, Stuckelberger, Eckhold, &c., that Enaux and Valentin devised those which bear their name, and that M. Roux (*Méd. Opér.*, t. I., p. 451) associated with the ordinary suture a square piece of adhesive plaster, provided with nooses of thread on each cheek, but which the bandage of Louis or that of Desault have caused to be entirely abandoned.

*II. Operative Process.*—As to the rest, the following is the mode to be adopted in the operation: the different articles are composed of an erigne, a claw or dissecting forceps, a pair of harelip scissors, three, four or six prepared needles, a simple waxed thread two to three feet long, a second thread composed of two to three strands and twice as long as the first, small rolls of adhesive plaster or linen to place under the extremities of the needles, a thin plumasseau of lint besmeared with cerate, two compresses somewhat longer than broad, and folded six or eight double, to be applied upon the cheeks, a band an inch wide and rolled into two heads and sufficiently long to make four or five turns round the head, the sling bandage, strips of adhesive plaster in case we do not wish to employ a bandage, a playing card, and a straight bistoury when we do not wish to operate with the scissors.

*a. First stage.*—The patient being placed upon a chair in a well lighted apartment, is to have his head steadily supported by an assistant, who is to prepare himself in such manner as to be enabled to compress at the same time the external maxillary arteries below and in front of the masseter, to push forward the cheeks towards the median line, and to hold the lip if it is necessary, while the operator excises it. A second assistant is charged with handing all the different articles according as they are required. The surgeon being seated or standing up in front of the patient, passes a thread through the lower left angle of the division, as Koenig recommended, should he not prefer to introduce there a pin or hook it up with an erigne, as M. Roux does, or more simply make use of the tooth forceps as I do, or of the forefinger and thumb, in order to secure it with the left hand. The scissors being held in the other hand, are immediately

carried to two or three lines higher than the upper angle of the fissure, and separate the whole rounded portion with a single cut, if possible, encroaching even a little upon the sound tissues in such manner as to make a fresh, straight, regular, and neatly incised wound. On the other side he stretches the lip itself by embracing or drawing upon it with the thumb and forefinger placed a little outside of the border which is to be excised. The scissors, which are to be directed as before, are to be raised at their point as high as the upper extremity of the first wound, and even a little higher, in order that the two strips which have been isolated, and which, by their reunion, represent a V reversed, may be found at the moment free from every adhesion, even at their nasal angle. Nevertheless, if at this point a pedicle should remain, it should be divided by a third cut of the scissors, and as high up as possible. Otherwise this part of the wound, being too much rounded, would not allow of an exact coaptation without difficulty.

*b. Second stage.*—In order to insert the suture, the operator again seizes the right side of the solution of continuity with the forefinger and thumb of the left hand. With the right hand he directs the point of a first needle upon the skin, at half a line above the vermilion border of the lip, and at three lines external [to the wound]; plunges it in somewhat obliquely from below upwards, from before backwards, and from the skin towards the mouth, in order that in traversing the tissues it may come out at the union of the two anterior thirds with the posterior third of the bleeding surface; then changes its direction; pushes it through the other lip, from behind forwards, from above downwards, and from within outwards, in such a manner that its place of entrance and exit may be as accurately upon the same line as possible, and that in its whole track it shall have made a slight curve whose convexity is directed slightly backwards and upwards. Its two extremities are immediately encircled by the simple noose of thread, prepared for this purpose, and which enables the assistant, who is charged with this, to stretch in a proper manner the whole extent of the lip, while the surgeon inserts the second needle. The latter needle, if we want but two of them, should be inserted at an equal distance from the first and the upper angle of the harelip. There is no necessity, as with the other needle, of making it describe a curve or traverse separately through the two halves of the division. It is therefore pushed in transversely with the right hand, while the fingers of the left hand hold the two borders of the wound in coaptation, taking care nevertheless to make it enter and come out upon the skin at about three lines from the solution of continuity. In making use of fine pins, of insect pins for example, I have often employed as many as five with advantage. The middle part of the double thread seizes the last immediately after. Conducted by the two hands the two halves of this thread envelope it afterwards with cross turns in figure of 8, are then brought forward by forming an X under the adjoining needle, which is surrounded in the same manner, and thus in succession from one to the other, until the thread is exhausted or the whole wound is concealed by the figures of 8 and X which it has furnished. To terminate this

operation its two ends are rolled up, in order to be fastened under the head or point of the upper needle.

*c. Third stage.*—The first thread having become useless is divided by the surgeon, who then places small protecting rouleaux between the integuments and the pins, together with the plumasseau of lint, and the adhesive plaster or bandage, if he has concluded to make use of them. In this case he applies the middle of the bandage on the middle of the forehead; carries the two heads under the occiput, crosses them and changes hands, brings them back below the ears, and upon the square compresses which the assistant maintains in front of the masseter muscles; arrives on the sides of the nose; makes a slit in one of the heads of this bandage, opposite to the wound, in order to insert the other there, and to cross them with greater facility; carries them back above the nape in order to cross them a second time, and to terminate by circular turns around the cranium. The sling bandage, which is to fasten the whole, is first applied to the chin by its middle portion. The two lower heads are then raised up in front of the ears, over the cheek compresses, and as high as the vertex, where they are attached. The two anterior heads which remain are to be carried backwards in order to cross at the occiput, and to be brought forward upon the forehead. At present, however, I dispense with every kind of bandage and find I can get along very well.

III. *Subsequent treatment.*—This being done, the patient is to be replaced in his bed, where he is to remain at rest without speaking or attempting the slightest movement of the jaws, during the space of three or four days. Broths and very light soups, weak wine and water, or any ptisan whatever, constitute his whole diet. At the expiration of three days, if everything goes on well, the upper needle may be removed; and on the fourth day that also below. The mass of nooses of thread, glued to the skin, and left in place for one or two days longer, enable the cicatrix to gradually consolidate. When the front part of the lip is entirely freed of them, we may substitute adhesive plaster, if any apprehension exists that the reunion is not yet sufficiently firm. About the ninth or tenth day the cure is usually complete. There will be no impropriety in beginning on the fourth to allow of soups somewhat more substantial, and to permit the patient to get up and walk. When the needles are fine and in greater number, they may be withdrawn much sooner, beginning on the day after the operation. They have not, to the same extent as the others, the inconvenience of ulcerating and of mortifying the tissues which surround them.

IV. *Remarks.*—Before commencing the operation it is almost always necessary to divide the *frenum* of the upper lip. It can scarcely be dispensed with when we make use of the scissors, except in cases in which the fissure has but little depth and is situated outside of the median line. The bistoury forms no exception to this remark unless we dispense with giving it a support. When using this latter instrument we place, after the frenum has been divided, a card as high up as possible between the maxillary bone and the lip. After having fixed, by embracing it at its lower angle, the left border of the harelip upon this card, we direct the point of the instru-

ment, held as a writing pen, to the spot where the incision is to begin, in order to plunge it in perpendicularly, then gradually to depress its handle and to cut with a single stroke the whole extent of the fleshy border included between the cutting edge of this instrument and the card which hinders it from penetrating into the mouth. In order to excise the other border the surgeon seizes hold of the lip outside of the division, unless he should be sufficiently practised to do with the left hand what he has done on the opposite side with the right hand; carries in every case the point of the bistoury to the upper angle of the first wound, and terminates the incision moreover on this side in the same manner as in the other. The compress which Lavauguyon placed between the lip and the gum, in order to prevent the *adhesions* of this last, already rejected by Le Dran as useless if not dangerous, and again proposed by Heuermann, is no longer employed at the present day by any person, any more than is the piece of sheet lead advised for the same purpose by Eckholdt. Cases where the lip has been separated to a great extent from the maxillary bone are the only ones which would allow of its being thought of. De la Faye and Mursinna, who recommend that we should commence with the highest needle, doubtless forgot that in that event the two labial extremities of the division incur the risk of not continuing upon the same line. De la Faye himself was obliged afterwards to exsect the deformed tubercle, which was the result of it in one of his patients. Without conforming entirely to the precept of Le Dran, or plunging the lower needle into the vermilion border of the lip, we ought however to recollect that at the distance of more than a line above it the reunion might not be complete and might leave a small notch below. If it did not penetrate nearly as far as to the buccal surface of the organ, the agglutination would be effected only in front. A groove or gutter of greater or less depth would continue behind, and render the success of the operation imperfect. The bleeding surfaces not being in accurate contact, nor pressed together in a uniform manner throughout their whole thickness, would favor hemorrhage. It is readily perceived, on the other hand, that there would be a disadvantage in traversing the two halves of the lip through and through. In making the needle describe an arc the object is to depress the tissues a little more upon the median line than upon the sides, in order thereby to reproduce as much as possible the tubercle or small projection which should naturally exist there. The curved or flexible needles would be incapable of fulfilling this indication, which has been particularly recommended by A. Dubois (Heurtault, *Thèse*, Paris, 1811.) Although, as a general rule, we should *excise* rather a little *more than less* and prolong the wound, as B. Bell has pointed out, as high up nearly as the nose even when the notch has but little depth, it will be found sufficient however, by removing the whole red portion or cicatrized border, to transform the harelip into a fresh wound with loss of substance, of an exact triangular shape, and the edges of which present in every part the same degree of thickness. It would however, perhaps, be well to make each border of the division concave, as recommended by M. Husson, the son, (*Thèse*, No. 185, Paris, 1836,) should it appear that the reproduction of the middle tubercle of the lip would without this expedient be attended

with too much difficulty. If the effusion of blood, which at first comes out with considerable force from the coronary artery, should not yield to pressure made on the facial artery on the border of the jaw, the assistant in order to arrest it would only have to pinch the corresponding half of the lip. Neither the ligature nor caustic are ever indispensable in these cases. As soon as the two bleeding borders are brought together the hemorrhage ceases ; their want of contact in one point or another, or some unforeseen accident, could alone enable it to continue. The surgeon moreover would be censurable not to pay attention to this subject during the first hours, especially in children. The blood, in fact, in place of being expelled outside, is swallowed by them in proportion as it oozes into the mouth, and as Platner says, the hemorrhage in this manner may go on to some degree unperceived, or may even, as in the examples given by J. L. Petit and Bichat, proceed to such extent as to cause death. Before applying the bandage it is well to *cover the head* with a cotton cap, drawn down so as to prevent its being disturbed without some difficulty ; also to comb out the hair well and to besmear it with mercurial or veratrum (cevadille) ointment, in order to prevent the necessity of scratching, which young patients could not resist should vermin make their appearance on the cranium.

The two compresses, which are placed in front of the ears, possess the triple advantage of crowding the tissues forward, rendering the bandage more supportable to the other parts of the face, and preventing the movement of the cheeks. Instead of making a slit in one of the heads of the bandage, to pass one within the other at the point of the wound, we may, if necessary, limit ourselves to crossing them carefully below the nose. The important point is, that they should not make any folds, and that the pressure which they exert should be as uniform as it is gentle. Louis cut the free extremity of his bandage into three strips of from fifteen to eighteen inches long, and also made in them three button-holes at nearly two feet beyond, with the view of effecting a more uniform and firm crossing opposite to the solution of continuity. Desault, on the contrary, rolled up his only in a single head, fixed it by a circular turn round the cranium, and when he had brought it as far as to the labial angle on one side, before carrying it back to the occiput, he strongly drew towards him all the soft parts of the opposite side, by means of the cheek compress, which without that precaution would have incurred the risk of being pushed backwards, contrary to the intention of the operator. But the ordinary bandage, whatever Bichat may say of it, has fewer inconveniences, while at the same time it retains the same simplicity as that of Desault. The sling bandage generally used is a very useful auxiliary in certain cases. By resisting the separation of the jaws, it favors the action of the suture. When we recollect that in a patient of Garengeot, a burst of laughter was sufficient to disunite the wound ; and that a young boy operated upon by De la Faye experienced the same accident in consequence of his sneezing, from a person taking a pinch of snuff near him, we may well be permitted to do all in our power to prevent the slightest movement of the mouth. In withdrawing the ordinary needles not until the expiration of five or six days, as is recommended by Garen-

geot, after having removed the threads, we have reason to apprehend that we may transform the track of the wound into a suppurating ulcer, and retard the ultimate cure. If they are taken away on the day after, or the day after that, as Le Dran assures us he has done without any inconvenience, it is almost certain that in the majority of cases the reunion will not be maintained. Moreover, not having yet had time to excite suppuration around them, their extraction then would not always be unattended with difficulty. In every case, when we are about to withdraw them, it is advisable to grease with butter, oil, or cerate, the extremity which is to pass through the tissues in coming out, that is to say, the point for the needles which have heads, and the blunt extremity for the others. They must be drawn out gently, and without shaking, turning them upon their axis as soon as any resistance is made, and constantly furnishing to the corresponding side of the lip, while we are removing them, a point d'appui with the forefinger of one hand. A small quantity of lint spread with cerate and some lotions of vegeto-mineral water are all that is required for the subsequent cure of their punctures.

B. *Complicated Harelip*.—I. In the *double harelip* two different conditions may be encountered if the vault of the palate does not participate in the deformity. Sometimes the two fissures are only separated by a narrow and slightly projecting tubercle, which must be removed by comprising it in the angle of reunion of the two excisions, which have been made in order to raw the ordinary harelip. Sometimes, on the contrary, this tubercle is too large to be destroyed without inconvenience. In such cases, whether it descend or not down to a level with the border of the lips, it is better to excise its two sides. We then pass through it all the needles in the first case, and the highest, or two highest only in the second, in order to attach it to the middle of the suture. This method, which is the most ancient of all, is at the same time the most simple, prompt and certain. If, however, the middle flap is very wide at its base, we may, after having embraced it at its summit with a first needle, traverse it with one or two others on each side, as M. Gensoul does, and as I have done in one instance. After the cure the cicatrix resembles a capital Y, and represents also the track of the naso-labial columna. It is scarcely perceptible to the patient that he has been made to undergo two operations in place of one. He soon recovers, and the consecutive inflammation is neither more nor less active than that which follows simple harelip. The idea, therefore, advanced by Louis or by Heister, of operating on one side only at first, and waiting for its complete cicatrization before proceeding to the other, though imitated since by some practitioners, has not been and ought not to be adopted.

II. The deformity, however, is sometimes much more complicated. It was so extensive in a worker in gold wire, mentioned by Covillard, (*Obs. Iatro-Chirurg.*, p. 86, obs. 29, 1639,) that there was a separation of two fingers' breadth on each side. *The portion of maxillary bone* which supports the middle flap, *makes*, in certain cases, a considerable projection forward. Like Dupuytren, (*Gaz. Méd. de Paris*, 1833, p. 6,) I have in such cases seen the raised up lobule continuous with the end of the nose, and projecting directly

forward. Whether it coexists or not with a double division of the palatine vault, we must attend to the complication before proceeding to the rest of the operation. Franco (*Traité des Hernies, &c.*, chap. 120, 121, p. 460 et suiv.) at first, then D. Ludovic, and afterwards Chopart and many of the moderns, have proposed to remove it either with the small saw or cutting pliers, or gouge and mallet, after having isolated the soft parts from it. Desault having remarked that this excision leaves a void behind the lip, which then no longer finds in this direction a convenient support; that there may, moreover, result from it so considerable a contraction of the superior dental arcade, that it ultimately becomes incased in the inferior dental arcade during mastication, an example of which he cites; proposed to preserve the osseous projection, and to limit himself to pushing it backwards by applying upon the anterior surface of the tubercle which it sustains a moderate degree of pressure during the space of two or three weeks. This method with him succeeded perfectly in many instances. Verdier and other surgeons have since obtained the same advantageous results from it. We should therefore adopt it in cases of simple deviations of the teeth the most approximated to the median line. To extract the projecting teeth after the manner of Gérard, and as most modern operators recommend, is an extreme remedy, which must not be decided upon until after having fruitlessly endeavored to restore them to their place, either by compression or by drawing them back towards the mouth by means of metallic wires fixed to the lateral teeth. Finally, it rarely happens that by means of precautions judiciously applied, and a little patience, that we do not succeed, in young subjects in causing these osseous projections to disappear without destroying anything. If the teeth, or the bone which encloses them, do not present in front either irregularities or angles too acute, the operation, nevertheless, may ultimately succeed. The reunion having been once effected, the pressure of the lip upon these parts suffices to give to them again, at the expiration of a greater or less period of time, their proper direction and position. In certain cases there would be an advantage also in proceeding after the manner of M. Gensoul, in a female in whom the intermaxillary projection, containing incisor teeth, had acquired a position almost horizontal, and after the manner of M. Champion (communicated by the author) in another case. M. Gensoul, after having dissected and reversed towards the nose the flap of soft parts, and removed the four incisors, seized the projecting portion of the bone with a strong pair of forceps, as if for the purpose of breaking it off, and succeeded in this manner in giving it a perpendicular direction; then depressed, in the same manner, the right canine tooth: afterwards excised the four borders of the double harelip, inserted the twisted suture into it, and maintained the whole by means of a bandage. This young patient, who was thirteen years of age, was perfectly cured. The bone thus consolidated, as well as the canine tooth, in the new position which had been given to it, and its border, which reached to the line of the molar teeth, became sufficiently firm to serve as a point d'appui to the inferior incisors during mastication. M. Champion, who dispensed with extracting the teeth, nevertheless succeeded perfectly well. In a newly born infant which I operated

upon with M. Rivallé, in 1837, I found that the median point, which sometimes makes an appendage to the lobule of the nose, had to be elevated posteriorly, in order to reproduce the nasal subseptum, and not depressed into the fissure of the lip.

III. The *simple fissure*, or that in the form of a capital Y, in the *maxillary vault*, to remedy which the ancients supposed nothing could be done, and which moreover prevented them from attempting to treat the harelip with which it is so often complicated, presents no obstacle whatever to the success of the operation, and requires in this respect, unless there should be too great a separation, no special modification in the process.

After the suture, the borders gradually approximate, and it sometimes, of itself, ultimately disappears completely, as is proved by examples which are already found in Roonhuysen, Sharp, De la Faye, Levret, (*Art. des Accouch.*, 3d edit., p. 252,) Quesnay, Richter, B. Bell, and Lapeyronie. In the instance noted by Gérard, this fissure, which was not less than a finger's breadth in width, closed up at the expiration of two years. Some few weeks were sufficient to effect this in a patient of Desault, and M. Roux mentions a child three years of age in whom scarcely any traces of a similar separation were observable at the expiration of the fifth month. The moderate but regular and constant pressure which the lip, whose continuity has just been re-established, exercises upon the whole external surface of the bones, is the cause of this truly remarkable phenomenon. Nevertheless, if it should be too tardy in being accomplished, either in consequence of the long standing of the disease or because of the very considerable chasm which the two maxillary bones leave between them, I do not see why we might not endeavor to favor it by means of compressing bandages either below the cheek-bone and on the skin, after the recommendation of Jourdain, (*Mal. de la Bouche*, t. II., p. 449,) and of Levret, (*Anc. Journ. de Méd.*, t. LXXXIX., p. 543, 40, 772,) though censured by Richter, but justified by Leblanc, (*Précis d'Opérat.*, t. I., p. 25,) or directly upon the alveolo-dental arcades themselves, as was done by me in 1825, or by embracing almost the entire head with Dent's bandage, or the ribbon dressing of Terras. There would be moreover a great number of modes of effecting this; and the object being once clearly ascertained, each surgeon would be enabled to devise the most suitable course to effect it. As in these different cases the lip has posteriorly but a very unequal point d'appui, and that any extraneous plate kept behind its posterior surface would have the serious inconvenience of irritating the parts, the bandage should be arranged in such manner that it would not exercise any great degree of pressure in front. It is unnecessary to add that the needles cannot be withdrawn with any degree of safety until the fourth or fifth day.

IV. *The most proper age for the operation.*—Another point still remains to be examined. Is it prudent to operate for harelip in the first months of infancy, or is it better to wait until the age of reason? This last opinion, advocated by Dionis and most of the surgeons of the 18th century, is almost exclusively adopted at the present day among us. The reason given for it is, that the young infant, incapable of assisting in the precautions that such an operation requires, cries

and becomes agitated and abandons himself to the most violent movements as soon as he is attacked. The mere sight of the surgeon or those who have approached him during the cheiloraphy, are sufficient to excite his terror and to throw him into a state of emotion. The slight degree of consistence and the little resistance of the tissues to the knife, (*sécabilité*,) occasion the points of sutures to be torn out upon the slightest degree of traction. The tongue, habituated to the efforts of suction, constantly presents itself between the lips, and more or less interferes with the reunion. The rigid diet which is necessary for several days sometimes produces, says Lassus, an emaciation so rapid that, at the expiration of 24 or 48 hours, the cheeks of the infant become flabby and all the portions of the suture greatly relaxed. Finally, it is a matter of very little consequence to the patient whether he is cured a little sooner or a little later, so long as he has not yet arrived at the period of talking. After the third or fourth year, however, the difficulty which he experiences in giving utterance to his thoughts, the raileries of his little comrades, and the consciousness of his own infirmity, naturally create in his mind a desire to be relieved of it. Then too, reasoning or entreaty or menace, have already begun to have a certain influence over him. He may then support the diet, and the density of the tissues is much greater.

To these arguments Busch, of Strasbourg, who with Roonhuysen, Sharp, Le Dran and Heister, had adopted the opposite opinion, replies, that we may prevent the cries and movements of the child by interrupting his sleep for several days beforehand, and by administering to him preparations of opium a short time before operating upon him, in order that he may become calm, and may sleep immediately after; that a child of three, six and even ten years of age, is often more difficult to restrain than if he was still at the breast; that the latter, entirely unconscious of fear, is affected only by real pain or wants, whereas the other recoils even at the suggestion of the slightest degree of suffering, and in reality attaches but very little importance to the results of the operation which is about to be performed upon him; that if in the first case the tissues are more easily divided and lacerated, this is compensated by their being better disposed to favor the completion of the agglutination with promptitude and certainty. I will add that when the suture is adjusted, the movements required for the introduction of a small quantity of milk or broth present but a very slight obstacle to the cure; while up to that period the harelip has scarcely permitted the little patient to become accustomed to sucking. The prolonged duration of the disease involves many more inconveniences than would seem to be imagined. It interferes with the development of the intellectual faculties by the impediment which it occasions to the pronounciation, and therefore to the employment of the ordinary means for education. When the separation of the vault of the palate is complicated with it, the longer we wait, the more the bones become separated apart, in consequence of the want of resistance from without. In this last case, sucking and even deglutition itself may be rendered extremely difficult, and death by inanition become unavoidable; examples of which exist. Moreover, in opposition to the arguments of Lassus, Sabatier, M. Roux, &c., we may oppose the daily practice of the Eng-

lish surgeons, the successful result obtained by Muys, Roonhuysen, Le Dran, Bell, Busch and Bonfils, (*Ephem. Méd. de Montpellier*, t. VI.—*Gaz. Méd. de Paris*, 1832,) on infants only some days or a few weeks or months old, and the three instances which have been published by M. Delmas, (*Ibid.*) It is moreover during the first months, and as near as possible to the period of the birth of the infant, that I would operate, unless I should think proper to wait till the termination of its first year of its infancy. As soon as the second year arrives, the patient having become more intractable, does not therefore possess more reason, and the inconveniences of his position, which are no longer of a nature to jeopardize his life, allow us to temporize for three or four years longer; thus I would choose the six first months of infancy, or from ten to fifteen years, as the proper time of operating for harelip; that is to say, I would rather recommend to those who have not been operated on in the first period, that they should wait for the second. If, however, the borders of the division were separated so wide apart as to render it almost impossible to bring them into contact, it would be useless to attempt the suture. I have seen it under such circumstances attempted without success in 1822, at the hospital of St. Louis on an infant about a month old; but it is doubtful if it would have succeeded better at a later period. Why not commence in serious cases by diminishing the intermaxillary fissure by means of a good compressor, similar to the spring that M. Pointe, of Lyon, (*Journ. Univ. des Scienc. Méd.*, Juillet, 1825,) in 1825, and M. Maunoir, of Geneva, (*Clin. des Hôpit.*, t. III., p. 48—*Gaz. Méd.*, t. I., p. 229,) a little later found to answer so satisfactorily? Why not separate the posterior surface of the two halves of lip from the bones as far as to the neighborhood of the cheek, in order afterwards to bring them together with greater facility, in the manner as had already been recommended by Franco, J. Fabricius, Horn, Nuck, Roonhuysen, &c.? In whatever manner the surgeon moreover proceeds, he should before taking the instrument in hand duly reflect, that notwithstanding all its simplicity, the operation for harelip requires skill and dexterity; that if he does not properly appreciate all the different stages of the operation, he will necessarily perform it badly, and to the same extent that it will confer honor upon him when he performs it in the most skilful manner, to the same degree will it be discreditable to him when he only succeeds imperfectly.

## § II.—Cancer of the Lips.

All kinds of cancerous tumors and degenerescences are neither more nor less capable of being cured in the lips than elsewhere. The ablation, when it is practicable, is almost the only remedy. It is doubtful, except in a few slight cases, if caustics, which are still employed successfully it is said by MM. Fleury, Patrix, (*Emploie de la Pâte Arsenicale*, 1816, in 8vo.) Hellmond, (*Bull. de Féruss.*, t. VI., No. 74; t. IX., No. 244,) Haime, (*Precis Méd. d'Indre et Loire*, 3e trimestre, 1817.) Chelius, (*Bull. de Fér.*, t. XIV., p. 79,) Magliari, (*Ibid.*, t. XIX., p. 284.) Heyfelder, (*Ibid.*, t. XII., p. 63,) &c., can be substituted for it, even though we should make use of the zinc paste eulogized by M. Conquoin, (*Bull. de Thérapeut.*, t. VII., p. 243, 375,) or the Eau Regale or chloruret of gold made trial of by

M. Récamier, (*Ibid.*, t. VIII., p. 300.) I have shown in another article what course is to be adopted when the maxillary bone itself is affected; I do not therefore intend, on the present occasion, to treat of any other matter than what concerns the soft parts. When the disease occupies only a small extent of the labial border, or that it extends more in a vertical than a transverse direction, the operation, which is as simple as it is easy, may be performed in two ways.

A. *Excision in V.*—The first consists in circumscribing the cancer by two oblique incisions in a triangular flap or sort of V, the base of which should correspond to the free border of the lip. The patient and the assistant are arranged in the same manner as for harelip. The surgeon embraces the morbid tubercle with the thumb and forefinger of one hand; while with a good pair of scissors or straight bistoury in the other, he forms his flap, taking care to cut into the sound parts and from the buccal opening to the point of the V, which he proposes to excise. The excision being now completed, nothing remains but to approximate the borders of the wound produced by it, to maintain it united by means of the suture, and to treat it in the manner of harelip. This method, the only one which has been for a long time followed, is applicable to the upper as well as to the lower lip, to its middle portion as well as to the angles of the mouth, and ought to be preferred so long as it does not become necessary that there should be any considerable loss of substance, or that we should destroy more than half, for example, of one of the lips.

B. *Semilunar excision.*—The other mode is still more simple in appearance. It resolves itself into a simple semilunar incision, which includes in its concavity all the diseased tissues, is made with the bistoury, or the scissors curved flatwise, and leaves as its result only a notch of greater or less depth. It is adapted only to the lower lip and when the disease extends less in a vertical than a transverse direction. Some modern surgeons have erroneously claimed the first suggestion of this process. It was in use at the time of Le Dran, and Louis mentions a patient who had been operated upon by this mode, and in whom it was said the lip had grown out again, (*était repoussée.*) Camper (*Prix de l'Acad. de Chir.*, t. IV., p. 585, 1819,) also gave it out as his invention. We find it even in Fabricius ab Aquapendente, who remarks very justly that we may in this manner remove a large portion of the lip, and that the deformity which results from it is infinitely less than one would be induced to suppose. However this may be, it was almost entirely forgotten until M. Richerand, A. Dubois, and Dupuytren revived it into credit among us. Two circumstances combine, after excision performed in this manner, to favor the elevation of the wound towards the dental arcade. These are the pressure outwards upon the sound tissues produced by the development of cancer, and secondly the gradual tractions which, at a subsequent period, the cicatrix exercises upon the integuments of the chin or even upon the upper part of the neck. It has been seen, in fact, that the surrounding soft parts, in persons who had in this manner lost the lip from one commissure to the other, and in the whole extent of its breadth, became elevated and sufficiently convergent towards the mouth to reach as far as to the

root of the teeth and even still higher. In the most fortunate cases the mucous membrane of the arch of the gums becomes united to the corresponding portion of the wound, and yielding to the cutaneous tissue which tends to draw it outwardly is reversed forwards, as if in order to furnish to the border of the new lip the vermilion pellicle which naturally belongs to it.

C. *Hem.*—This process however is not as good as the first; when using this the cure is always less prompt and the deformity always more perceptible. Consequently it should be reserved for exceptional cases. An improvement which might be made in it, and which M. Serre has already employed in practice, would consist in immediately uniting the mucous border with the cutaneous border of the wound, or as I have successfully done, bring it down in form of a hem by means of the simple or whip suture. We should in this manner procure in three days, a cicatrix more pliant and neat than that which we could get from the ancient mode in a month.

D. Under the most *unfortunate circumstances*, a greater or less extent of the jaw remains exposed after a removal of cancer of the lip. Speech then becomes imperfect, and the patient constantly losing his saliva, is placed under the necessity of wearing a metallic apparatus to the chin furnished with a sponge. Fortunately however at the present day, we are in possession of other modes of avoiding this inconvenience. (See Cheiloplasty.) It is important however, to remove in good season and freely, cancerous tumors of the lips; otherwise they repullulate in the neighborhood and below the jaw with frightful rapidity. A peasant of a robust appearance, in whom I removed one which did not exceed in size a small nut, died at the expiration of eight days with hundreds of cerebriform granules in the liver!

### § III.—*Eversion (Reversion) and Mucous Bourrelet.*

The lumps, and especially the species of red-colored ridge which many persons have on the internal surface of the free border of the lips, is a deformity which has been hitherto paid very little attention to in surgery. They are sometimes seen in the upper lip, which is most predisposed to them, sometimes upon the lower lip, and occasionally in both lips at once. In certain cases, under the form of one or many tubercles that are scarcely perceptible, at other times under the aspect of a transverse projection, which strongly pushes the lip towards the skin as soon as the patient attempts to laugh or speak. Though it is usually a congenital defect, it sometimes occurs accidentally, especially in persons who play the horn or are obliged to cry with great force. Their presence has nothing dangerous and involves no other inconvenience than that of rendering the countenance somewhat less agreeable. Also, most of those who are affected with them, have them all their lives without ever thinking of getting rid of them. Nevertheless in certain classes of persons they become embarrassing, as in hunters, musicians and orators for example. Instances of this kind are seen in the two patients who were operated on in 1829, by M. Roux and Boyer. They are, however, cured with great facility. They are to be excised either with the

scissors curved on the flat side or with the ordinary bistoury. While an assistant stretches the lip at its two angles, and exposes its inner surface to view, the surgeon seizes hold of as much of the vegetation as possible by means of a good pair of forceps placed transversely, raises it up a little, and afterwards proceeds as in the excision of the bourrelet of the conjunctiva in ectropion. Numerous cases from different authors, or those mentioned in the lessons of Dupuytren, show that at the end of a week or two the cure is complete, and that the deformity which has been thus treated, has entirely disappeared. Nevertheless, as there are in this part under the elongated tissues numerous hypertrophied mucous glands, which glands and follicles it is necessary to remove, and as I have seen the wound in certain persons take on a bad aspect, and require nearly three weeks or a month to cicatrize, I have adopted another method. Having seized the mucous fold with a pair of forceps, I pass through its root or base near the muscular tissue, three or four threads which I leave there. I then immediately excise the bourrelet near these threads, after which I have nothing more to do than to knot the points of the suture, which may be removed on the second or third day. The same operation would be equally applicable without doubt, to the eversion of the lips produced from any other cause, as for example, by bridles or ancient cicatrices, so true it is that this condition of the mouth has the greatest degree of analogy to ectropion or eversion of the eyelids, and that it is susceptible of the same surgical remedies.

#### § IV.—*Hypertrophy of the Lips.*

The thickening of the upper lip, which may be considered almost a natural result in scrofulous subjects, may exist to such extent as to constitute a serious disease if not a disagreeable deformity. In certain cases the totality of the lip acquires so great a degree of development that its posterior surface ultimately becomes reversed downwards and its free border directly forwards. So long as there is a morbid action going on and that the hypertrophy is not positively established and not reduced to the condition of a simple defect of conformation, we should confine ourselves to internal or external treatment and to the proper general or topical remedies. But when all the resources indicated by a sound therapeutic have been employed in vain, and that the affection has become purely local, there is no other than the cutting instrument which can destroy it, unless we should be disposed to make trial of compression and caustics. The operation which is proposed for the relief of the patient was suggested, in 1826, by M. Paillard, (*Journ. de Progrès*, t. III., p. 213.) who performed it in three instances with entire success, and who gives three other examples of a fortunate issue obtained in the same manner, by MM. Marjolin and Belmas. It consists in un-doubling the lip and reducing it to its normal dimensions by excising a layer from its tissue of greater or less degree of thickness. The assistant charged with supporting and holding the head of the patient back against his chest, is also made to stretch the part and cause it to project outwards by seizing it at the left commissure with the forefinger and thumb of the corresponding hand. The operator placed in front

and a little to the right seizes hold of the other commissure, then with a bistoury in his right hand makes, from one labial angle to the other, and perpendicularly on the border of the diseased lip itself, an incision which is slightly somewhat more approximated to the mucous membrane at its extremities than at its middle; in this manner circumscribes every thing which it is his intention to remove; immediately embraces this flap with the forceps and dissects it rapidly with the same bistoury from the free to the adherent border, and from the left to the right extremity of the part, down to a level with the sound tissues; endeavors to give it all the breadth and thickness required, while taking care to approximate it gradually to the mucous coat before terminating the excision near the alveolo-labial groove with the last cut of the bistoury or a good pair of scissors. The wound which results from it sometimes bleeds copiously, though in general it yields with facility. No kind of dressing is necessary, inasmuch as the traumatic surface, from being continually lubricated by the saliva, becomes rapidly cleansed. In cicatrizing it reacts upon the integuments, gradually brings them forward, or even tends to incline them downwards, and in cases of complete cure, the lip not only returns to its natural thickness, but also to its normal direction.

#### § V.—*Various Tumors.*

M. D. Lasserre, by excising in this manner from the upper lip, was enabled to remove an enormous fibrous tumor. A boy aged fifteen years was brought to me from Vaugirard by his father, in 1836, to the hospital of La Charité, for an elephantine tumor, which he had had upon his upper lip for the space of three years. This tumor, which was badly defined, half the size of an egg and indolent, occupied the entire thickness of the lip and did not, after having been removed by the V excision, return again in the manner of cancerous tumors. Sebaceous and mucous cysts, those that are serous, and all the descriptions of tumors which I have elsewhere described, are quite frequently met with on the lip. An erectile tumor was extirpated from this part with entire success by M. Pl. Portal, (*Clin. Chir. &c.*, pp. 139, 144.) Under the chapter on *erectile tumors* I have described the number of processes that have been adopted for those of the lips. M. Pl. Portal also states that he successfully extirpated one that was situated upon the chin.

#### § VI.—*Atresia and Contraction of the Anterior Opening of the Mouth.*

Boyer, who says that he never saw an instance of imperforation of the mouth, was doubtless unaware of the fact, that Haller had mentioned several instances in the human species and in animals; that Monro had noticed this imperforation in young pigs, and that Verrier (*Abrégé d'Anat.*, t. II., p. 124,) states he had seen an instance in a dog. This last author also relates, on the authority of Gregoire, an instance of a newly born infant who had neither mouth nor nostrils, though it was born alive. Schenckius, (*Planque, Bibl. de Méd.*, t. I., p. 305, in 12, art. *Accouch.*.) had already mentioned that he had met with

infants in whom he was obliged to lay open the mouth, and Desgenettes (*Gaz. Salut.*, 1792, p. 95,) states that he had seen a seven months' fœtus in which the mouth was imperforate. It is shewn, therefore, by these facts, that imperforation of the mouth may be congenital. Other observations prove that it may also take place after birth. G. Horstius (Turner, *Mal. de la Peau.*, t. I., p. 120,) relates that in a miller, the lips, after having been excoriated, became glued together. A small hole which had previously allowed of the introduction of aliment into the mouth, by means of a funnel, itself ultimately closed up, so that the poor patient starved to death. Though the entire obliteration of the mouth may be infrequent, it is not so with simple contraction, or coarctation of the lips. This contraction, which, like imperforation, may be either acquired or congenital, may result, moreover, from various descriptions of diseases. A newly born infant mentioned by Demarque, (*Op. cit.*, pp. 449, 450,) had the opening of the mouth so small that it was scarcely possible to introduce a pea into it. Another individual mentioned by the same practitioner, had the mouth contracted to the extent of a finger's breadth on each side, in consequence of small pox. Demarque (*Traité des Bandages*, p. 447,) mentions also a woman and child in whom the opening of the mouth was in this manner almost entirely closed, in consequence of burns. When the imperforation is complete, as in the patient of Buchner, (Planque, *Bibl. de Méd.*, t. XVI., p. 166,) or in that of Percy, (*Memoire sur les Ciseaux*, § 5, p. 70,) we must in the first place incise in the direction of the natural opening, and upon the part of the cicatrix which appears to be the thinnest. As soon as the bistoury has passed into the mouth, it is well to replace it by the scissors, one of the blades of which is to be inserted through the small opening which has just been made. Percy succeeded in this manner in the young Count D'Ambly. The operation was also followed with entire success in the child mentioned by Buchner. In those cases, on the contrary, where an aperture still remains, the operation is manifestly more easy, since it is always then practicable to follow with the eye as far as into the mouth, the instruments that we make use of. I will not recur again to the methods which present the best chances of success in such cases, and which I have described in the chapter on anaplasty. I will refer only in proof of the difficulty of curing coarctation, or imperforation of the lips by simple incisions, to the history of the miller of Horstius. The lips of this patient, in fact, after having been separated by the instrument, obstinately reunited a first, second, and even a third time. We also find in a case of M. Bondi, (*Bull. de Fér.*, t. II., p. 69,) that the incision made in order to destroy a coarctation of the lips, did not prevent the infirmity from being re-established to so great a degree in fact, that the opening of the mouth was reduced to the diameter of a pin's head, and that death succeeded at the termination of a few days, during a paroxysm of asthma. It is, however, to be remarked, that in the patients mentioned by Demarque, this operation appears to have fully succeeded, and to have been unattended even with any difficulty. (See Cheiloplasty.)

### § VII.—*Too Large an Opening of the Mouth.*

In the Germanic Ephemerides, (*Bull. de Féruss.*, t. II., p. 69,) we find the history of a child in whom the mouth extended as far [nearly] as the ears. Having operated upon one side, an interval of some weeks was left before doing the same for the other, in consequence of the first operation having produced an alarming hemorrhage. I do not know to what extent it is possible for the mouth to reach up to the ears. I have, however, myself seen an old man in whom the mouth had been enlarged as far as the anterior border of the masseter muscles. This man had entered the hospital of La Charité for a double cancer, which obliged me to remove almost the entire length of the free border and the whole of the commissures of the lips as far as to the cheek-bone. The union of the parts had been effected by means of numerous points of twisted suture. But in consequence of an erysipelas, accompanied with intense delirium, which supervened on the third day, the patient, in separating his jaws with force, speedily destroyed and tore out the suture, together with the first agglutinations, which had already begun to take place. As the general affection continued nearly fifteen days, the lips of each wound cicatrized separately. In consequence of which there resulted a hideous deformity, which prevented the unfortunate old man from entirely closing his mouth, or from being enabled to retain his saliva effectually, or from performing mastication in a proper manner. It might have been practicable or even easy, by abrading the borders of these enormous prolongations of the mouth, to unite them by suture, and in this manner destroy the deformity; but the patient, satisfied with the cure of his cancer, and weary of his sojourn in the hospital, was desirous of returning home, and positively refused every proposition for another operation. As to the remark, that the mouth is either too large or too small when there are no traces of cicatrix or degenerescence upon the free border of the lips, this can scarcely be conceived to be possible, inasmuch as the natural dimensions of this opening have not and cannot have anything absolute about them; unless we should admit with G. D. Tholosin, (*Gaz. Salut.*, 1766,) "that the mouth (in every person) should be limited to the exact length of the first bone of the thumb." Operations, therefore, cannot be required except for extraordinary cases of narrowness or enlargement, which are produced by certain diseases.

### § VIII.—*False Anchylosis.—Stiffness in the movements of the lower jaw.*

Temporo-maxillary arthropathy, like all those diseases which may be developed around or in the neighborhood of the condyles of the jaw, are capable of producing there an induration or stiffness to so great an extent, that the separation of the dental arcades will be thereby more or less impeded. Certain chronic inflammations of the windpipe, internal phlegmasias at the bottom of the mouth, those especially which take place in the neighborhood of the last molar tooth, may also sometimes give rise to the same infirmity. The patient in such cases cannot open his mouth. Various methods of cure are then resorted to.

A. M. Ghidella, and some other practitioners, who assert that they have succeeded by making numerous incisions upon all the indurated ligamentous or cellular plates, could only have encountered those anchyloses, which are produced by retraction of the fibrous tissues. In my own opinion, it would not be prudent to recur to this process, unless the fibro-muscular bridles should be distinctly perceptible through the integuments. Ténon, (*Mém. sur l'Anat. et la Chir.*, t. II., p. 261—262.) who saw a case of this kind, resulting from a deep-seated disease of the jaw, and afterwards another, which admitted only of a separation of some lines in extent, had recourse to the employment of wedges of cork. The defect of conformation was congenital; after having divided one of the labial commissures, it was found that a cicatrix formed and reduced the opening of the jaws to two lines. Ténon insinuated between the teeth two wedges of cork, the thickness or number of which were gradually increased, until the mouth could be opened to the extent of nine lines in place of two.

B. *Dilating wedge*.—This idea, of placing a wedge between the dental arcades, has been improved upon by M. Toirac, (*Mem. sur la dernière Dent Molaire*, p. 13, 1828,) who has obtained really successful results from it in different patients whom I have seen, and who had been, during many months, unable to separate their teeth beyond a few lines. The remedy moreover is simple and of easy application. We begin by a thin and very elongated wedge, which is to be inserted between the two dental arcades, nearly as far as to the coronoid process; the size of this wedge is to be daily increased, until the movements of the mouth have regained their extent and liberty. It is obvious, however, that the presence of a cork or wooden wedge between the dental arcades can scarcely present any hope of success except in cases of immobility unaccompanied with unnatural adhesions of the gums with the inner surface of the cheeks or with actual ankylosis of the articulation.

C. *The wedge and incisions*.—M. Mott having met with many obstinate and complicated cases, has devised an instrument, which acts at once in the manner of a wedge, lever, and saw. This instrument which might, if necessary, be made to divide the coronoid process or the root of the neck of the condyle of the jaw, possesses the power, as a wedge and a lever, of gradually widening, and with a great degree of force, the two maxillary bones. The surgeon whom I have just cited, and who performed this operation successfully on seven different patients out of the eight that came under his treatment, was obliged in some cases to divide the commissure of the lips largely in the manner of Ténon, and to leave each border of the wound to cicatrize separately, not reuniting them until after having completely re-established the movement of the jaws. This is an operation, however, which, notwithstanding what has been said of it on the authority of M. Mighels (*Gaz. Med.*, 1834, No. 26,) and of M. Mott, (*Journ. de Progrès*, t. XIII., p. 925,) and what the author has recently written to me concerning it, is still too imperfectly understood among us to enable me to affix to it its just value. [See chapter on this subject by V. Mott, *infra*. T.]

### § IX.—*Unnatural adhesion of the Cheeks.*

It frequently happens in consequence of mercurial, carbunculous, or other inflammations, and as the result of any other kind of ulcer which may occur in the mouth, that the inner surface of the cheeks becomes agglutinated to the outer surface of the jaws or gums. From whence happens a deformity analagous to that I have just described, that is to say, an impediment to the separation of the jaws and the movements of the mouth. These adhesions sometimes make such effectual resistance to the movement of the jaw, that it is impossible for patients to open their mouth. Numerous examples of this are related in scientific works, and I have myself met with some of them. In appearance nothing is so easy as to remedy this disease; in reality nothing, however, is more difficult.

A. *Décollement*.—The first idea which suggests itself is to attack and destroy, either with the scissors or bistoury, the bridles and cellular attachments which constitute the abnormal adhesion, and without interfering with the continuity of the tissue proper of the cheek. But in reflecting on this point we soon perceive that this dissection, which as an operative process presents no difficulty, and in fact momentarily destroys the deformity, can only effect a radical cure in exceptional cases. What prevents the outer side of the gums and inner surface of the cheeks from agglutinating together in the natural state, is the existence of the mucous membrane which lines both of them. Now this mucous membrane, which has disappeared in the cases of adhesion, cannot be reproduced by the dissection which I have just mentioned. It must result, therefore, that the incisions which have been made will, in cicatrizing, reproduce the deformity. In even admitting that the entire traumatic surface may have cicatrized upon the cheek, independently of the gums, it could only do so at least by the production of an inodular callous and inextensible tissue, which in itself would be calculated to interfere excessively with the separation of the jaws. This difficulty is met with in all the other modes of operation which have been proposed as a remedy for the closure of the jaws. It is important therefore that we should not deceive ourselves on the subject of the apparent simplicity of this deformity, any more than we should upon the efficacy of the means which we may have it in our power to oppose to it.

B. However this may be, there are many processes to be made trial of in such cases. The most simple is that which I have attributed to *M. Toirac* in the preceding paragraph, and which consists in forcibly separating the jaws by means of wedges successively augmented in size, and introduced to a great depth into the most remote part of the dental arcades. This means, when there is no rigidity in the tissues or when the adhesions are recent and of but little extent, will suffice if continued for the space of fifteen days or a month, giving a respite of some hours to the patient from time to time, and resumed afterwards from week to week.

C. *The process of M. Mott*, that is to say, the introduction of a wedge performing the office of a saw and lever, in such manner as to allow of the division of the bone if necessary, would become requisite should the jaw be ankylosed or surrounded with inodular

tissue endowed with a great degree of resistance. The instrument of the surgeon of New York would also have its advantages as an auxiliary means, when it becomes indispensable to destroy the internal adhesions of the cheek or lip, with the cutting instrument. This last method comprises three principal processes.

*D. Simple dissection of the adhesions.*—The most rational method apparently, would consist in destroying by means of a straight or blunt-pointed bistoury, glided upon the finger or a canulated sound, or even without a director, from above downwards between the cheek and lower jaw, and then from below upwards between the cheek and upper jaw, all the abnormal adhesions to a sufficient extent, and in such manner as not to arrest the knife until after having reached as far as the pliant and perfectly sound tissues of this region. In this manner the operation is easy and prompt, and the immediate result of it as satisfactory as possible. The patient is to be seated upon a chair. The operator, separating one of the commissures with the forefinger and thumb of one hand or a good forceps, directs his bistoury with the other between the two dental arcades as far as to the neighborhood of the coronoid process. Turning then the edge of his instrument towards the outer surface of the teeth, he divides with free strokes and in a direction parallel to the plane of each jaw, all the bridles and unnatural tissues which attach them to the cheek. Should the teeth be so approximated as to prevent the instrument from gliding between them, he should make use of a canulated sound in order to conduct it outside of and along the alveolo-zygomatic (alvéolo-jugale) groove. It would even, if necessary, be practicable to plunge it into the tissues from before backwards, if there should be no groove to admit of a free passage to the director. Having reached this point we have now to struggle against the tendency of the wound to reagglutinate. To attain the object in these cases we have need of two kinds of resources; in the first place we must procure, by means of wedges or levers, a sufficient separation of the jaws, and it is for this purpose that the wedges and levers of MM. Toirac and Mott are indicated. If in fact we did not commence by giving a great degree of freedom to the movements of the lower jaw, new adhesions and an almost insurmountable contraction of the tissues would not fail to take place. On the other hand, we cannot prevent the inner side of cheek, now transformed into a traumatic surface, from becoming reunited to the outer side of the gums, except by keeping some foreign body between them. Ténon, in the three cases which I have quoted from him, and which relate rather to the adhesions under consideration than to a false ankylosis, appears to have succeeded by means of pieces of cork fastened by the aid of catgut against the outer side of the teeth. It is to be confessed, however, that we rarely succeed in this manner.

A young girl aged sixteen years, who, in consequence of a carbunculous (charbonneuse) affection of the mouth, had had from her birth a complete adhesion of the cheek and the right half of the lips to the dental arcades, and who was admitted into the Hospital of La Charité in the month of January, 1836, had already undergone two operations of this kind without any benefit. I in my turn destroyed all the abnormal adhesions, and I succeeded in procuring a separa-

tion of fifteen lines between the jaws in the space of a week. A piece of sheet lead, protected by cork, and kept permanently between the teeth and the cheek, appeared to me calculated to prevent any new adhesion. After the cure, however, there resulted only a slight amelioration, and a separation of only from three to four lines. It is necessary however to add, that the young girl evinced an extremely intractable disposition, and that in consequence of a confluent small-pox, with which she was attacked at the expiration of a month, I was compelled to remove every portion of the dressing or foreign bodies from the interior of the mouth before the perfect cicatrization of the wounds. A young man who had similar adhesions, which M. Serre had previously destroyed by a crucial incision in the cheek, and which I treated in the same manner in 1837, was not less unfortunate. After having carefully dissected and isolated the inner surface of the cheek throughout its whole extent, and after having sufficiently widened the jaws by means of levers and wedges, I inserted in his mouth a broad piece of sheet lead, upon which I intended that the wounds should cicatrize uniformly in every part of them. Every thing at first went on as well as I could wish, and at the expiration of five weeks, I considered my patient cured. The dispensing however with the use of the plate of lead during the space of two days, caused the separation of the jaws to be diminished one half, and nothing afterwards could prevent the inodular tissue from reproducing the deformity to as great a degree nearly as before.

E. Like M. Mott, I also was desirous in one case to ascertain if I could succeed better *by laying open the whole cheek* from the commissure as far as to the masseter muscle, and afterwards dissecting each of the borders of the incision, and leaving them to cicatrize separately in such manner as to reunite them at a later period, as we do in harelip. The cheek being thus separated, no longer interferes with the movements of the jaw, which can afterwards be relaxed and widened by the proper mechanical means. Having once obtained all that we desire in this respect, we reunite the borders of the artificial division. As the internal surface of each of the flaps has had time to cicatrize, we need have no farther apprehension that it will reagglutinate to the outer side of the gums. This method, which had failed in one of the patients of Ténon, and which succeeded no better with me, nevertheless procured some successful results with M. Mott. It would therefore be a process to be made trial of as well as that of simple décollements, which, united with cauterizations by nitrate of silver, obtained a remarkable cure in the hands of M. Gensoul, (*Journ. des Hôp. de Lyon*, t. I., p. 494.) I believe moreover, that by means of determination on the part of the surgeon, and docility on the part of the patient, we could very frequently obtain cures by both these processes; but I repeat that success here is infinitely less difficult to be accomplished than would at first view be imagined. We should be wrong moreover not to anticipate a swelling and sufficiently marked inflammation of the cheek and a large portion of the face, when, after such separations, we decide upon placing any foreign body between the cheek and the teeth with the view of preventing all reagglutination. Perhaps it would be better, should there be any inodular productions implicating the skin,

to remove them, and immediately repair the loss of substance by means of genoplasty, in taking a large flap in the neighborhood, as was done successfully by M. Mott. (*American Journal of Medical Sciences*, Nov. 1831.)

#### ARTICLE V.—SALIVARY FISTULAS.

There is no end to the remedies that have been devised for the cure of salivary fistulas, and most of them, we must admit, have been attended with some success.

##### § I.—*Fistulas of the Parotid Gland.*

A. *Cauterization*, either with a hot iron or by means of chemical substances, as employed by Galen, on a patient in whom the fistula, the result of a critical inflammation of the parotid glands (*suite de parotides critiques*), was situated under the ear; and as employed by Paré, the two Fabricii, Heuermann, Boyer, Langenbeck and a multitude of others, succeeds very well for fistulas of the parotid itself, that is to say, those which derive their origin from some branches and not from the principal trunk of the excretory ducts of the saliva. Galen had recourse to cathartic plasters (*emplâtres cathérétiques*), Paré to aqua fortis, Diemerbroeck and Jourdain to the actual cautery, M. Higginbottom (*Bull. de Fér.*, t. XXVI., p. 95), to sulphuric acid, and Boyer to nitrate of silver. The lapis infernalis deserves the preference, because it produces a drier eschar and one which is more adherent than any other. Nevertheless if the ulceration should be narrow and very deep, a cautery of the red oxide of lead might be substituted for the nitrate of silver, as was practised by me with success, in November, 1831, at La Pitié, in a man who had a parotid fistula produced by the opening of an abscess behind the border of the jaw.

B. *Blisters*.—*Styptics* and astringents, which were equally eulogized by some practitioners, Becket among others, being less efficacious than caustics, have been long since abandoned. I have cured two patients, who had been affected several months with parotid fistulas, by means of repeated temporary blisterings upon the diseased parts.

C. *Compression*, made trial of successfully by Beaupré, Le Dran and Ruffin, who invented a machine for this purpose, advocated also by Imbert, Jourdain and Richter, almost always answers the purpose when the patient can support it, and when the state of the parts permit its employment. For that purpose we apply lint or graduated compresses upon the fistulous orifice, after which, by means of a fronde or chevestre bandage, or by means of turns of the ordinary bandage properly arranged, we produce pressure on this point in such manner as to keep the walls of the diseased duct in contact.

D. *Irritating injections*, as proposed by Louis, have for their object to inflame the fistulous passage and to bring about its agglutination. They may be made with sweetened barley-water, decoction of French roses in red wine, alcohol itself or any other exciting liquid, according as the tissues, whose adhesive inflammation we wish to produce, are more or less irritable. It is a remedy however which comes only in the third class, because it exposes to more acci-

dents and is not always successful, but one which, in some cases of obstinate fistula, is not to be despised.

E. If none of all these succeed, we may make trial of *excision*, comprising the ulcer in an elliptical wound, and afterwards reuniting by means of adhesive plasters or the twisted suture. If the disease still resist, we have no other recourse than *extirpation* of the gland; but this remedy, ascribed to Pouteau, by M. Hedelhofer, has never, I believe, been carried into execution. It would be, in fact, a case in which the remedy is worse than the disease; so much the more so as these fistulas sometimes finally disappear spontaneously, examples of which are given by Nuck, Ferrand, A. Dubois and M. Richerand.

## § II.—*Fistulas of Stenon's Duct.*

These different modes of treatment, though less efficacious when applied to fistulas of Stenon's duct, have nevertheless, in some cases, effected unquestionable cures.

A. *Cauterization*, for example, alone or associated with compression, obtained for Louis an unexpected cure, in a patient in whom the fistula had existed for the space of nineteen years, and who had already been operated on several times without any benefit. Municks, (*Praxeos Chirurg.*, lib. II.,) Lentilius, Lange, (*Bibl. Chir. du Nord*, p. 135,) and Mosque. (*Ancien Journ. de Méd.*, t. LXXI., p. 506,) have or had also succeeded in the same way. Ferrand, Nédél, Mursinna, Imbert, Jourdain and M. Langenbeck have been no less fortunate. But M. Gendron (*Annales de Cercle Méd. de Paris*, t. I., pp. 55, 92) has since maintained that in all the cases of this description the fistulas were in the gland and not in the salivary duct.

B. *Compression* without caustic and as an exclusive remedy, has also appeared to have been efficacious. Maisonneuve, who was the first to recommend it in such cases, established it between *the fistula and the gland*, with the rational object of closing up the passage to the saliva and enabling the wound to cicatrize. His patient, who had received a sabre cut upon the cheek, was radically cured at the expiration of 20 days. Louis, and with him most of the moderns, have considered that by acting in this way, we almost necessarily produce inflammation of the parotid, and that consequently this process cannot but be dangerous. Desault hoped to dissipate all these apprehensions by directing the compression *upon the gland itself*, which he proposed to atrophize. Whether the atrophy had really taken place as Desault asserts, (Gavard, *Splanchnol.*, p. 208,) or that the parotid continued to perform its functions afterwards, as Boyer seems to think, certain it is that the fistula speedily cicatrized and that the patient suffered no return of it. However this may be, there is in the treatment of these authors, two distinctions which it is important not to confound; that of Maisonneuve, who proposes only to interrupt the course of the saliva temporarily, and that of Desault, (Vedrine, *Journ. de Desault*, t. IV., p. 294,) who prefers to dry it up at its source. Without agreeing with Heuermann, that the parotid, under such circumstances, will always suppurate and ulcerate, and pass into the state of scirrhus or cancer, I can nevertheless not admit the innocuousness of a remedy like this, which should in my opinion be reserved

for patients who have a dread of every other kind of operation, or have not been cured by them. Trécourt (*Mém. de Chir.*, p. 75, 1769,) had recourse to it by applying it upon the ulcer-like Courtavoz because the seton was not admissible.

C. *Ligature upon the duct.*—Zang, who shares in part the opinion of Maisonneuve and Desault, resorts to the process of Viborg, to atrophize the parotid. In place of compression, which is always uncertain, this surgeon, inasmuch as the object is to prevent the saliva from passing, proposes to apply a ligature on the duct of Stenon outside of the fistula. Quite a number of experiments upon animals towards the close of the last century, demonstrated to him that this ligature is unattended with danger. In order to apply it, it would be necessary to make a vertical incision upon the anterior border of the masseter, immediately below the zygomatic arch. The canal being once laid bare, is to be isolated from the other tissues, especially from the branch of the facial nerve which accompanies it on its upper side. Nothing afterwards is easier than to surround it with a ligature, and obliterate it. There is no doubt in principle that if the sacrifice of the functions of the parotid gland has been decided upon, the advice of Viborg should be followed to the exclusion of that of Desault and Flajani, if it could be proved that the saliva would allow the ligature to effectually obliterate the duct in this manner; but compression, presenting moreover the advantage of requiring no incision, will notwithstanding be adopted in preference, by timid and pusillanimous patients: whence it follows that these two methods might each become susceptible in practice of particular application.

D. *The twisted suture*, as in harelip, when the anterior portion of the canal remains unaffected, answers, according to Flajani, Percy and Zang, in many persons, and in most cases renders any other means unnecessary should it be applied in good season. M. D. Lasserve (*Cas. de Chir.*, p. 27, Perigueux, 1830) having wounded the canal of Stenon while extirpating an osteo-fibrous tumor of the cheek, made at the bottom of the wound an opening of two lines which penetrated into the mouth, and the lips of which he successfully united by suture. M. Pl. Portal (*Clin. Chir.*) having extirpated a salivary tumor, was no less successful in another case. The same occurred to M. Bégin, (*Pathol. Chir.*, t. I., p. 209, 2d edit.)

E. *Seton through the natural duct.*—Morand first, and Louis afterwards, are the two authors to whom we are indebted for the idea of dilating Stenon's duct for the cure of its fistulas. The surgeon being placed in front of the patient, seizes the labial angle by means of the thumb introduced into the mouth, and the two first fingers of the left hand applied upon the cheek if the fistula is on the right side, and with the two fingers of the right hand, if it is situated on the left; stretches it and reverses to the outside; introduces with the other hand the head of a fine probe, furnished with a thread, into the natural orifice of the parotid duct; withdraws it through the wound, where he leaves the little seton whose two extremities he unites by a knot, and by which he is enabled on the day after to draw into the mouth from the exterior to the interior a small cord of silk; and each day renews this meche by withdrawing it through the wound and by adding to it each time one strand more. Should it be attended with too much

difficulty to penetrate through the mouth, Louis proposes that we should immediately introduce the probe through the wound. It must be almost a matter of indifference, in fact, whether we enter by one mode or through the other.

In this last case, however, the thumb should be substituted in place of the fingers, in order to straighten the canal and to incline its orifice forwards when the probe is about coming out; not because it makes an angle while it traverses the buccinator muscle, as is generally thought with Louis, but because it falls at an acute angle on the mucous membrane, which shuts it up in great part and appears to throw its aperture backwards to the extent of a line. As soon as the saliva passes freely into the mouth, and the ulcer has become contracted up to the periphery of the meche, the seton is to be removed, or what is preferable it is to be divided upon a line with the integuments, in order to draw it towards us by its buccal extremity to the distance of about a line, and not to take it away entirely until after having completely closed the fistula by means of repeated cauterizations and drying applications.

*F. Seton through a new duct.*—If it were always easy to find the anterior end of the divided canal; if it were not that this canal in most cases has been for a long time obliterated when the physician is called for; if, in fine, its preservation was a matter of much importance, the process of Louis accurately imitated from the method of Méjean in the treatment of fistula lachrymalis, would certainly have obtained unanimous concurrence; but this is not the case, and the following is the method which almost all operators at the present day have recourse to.

I. *Deroy*, who, according to *Saviard*, appears to have invented this method, pierced the cheek through and through with a hot iron, thus obtained a loss of substance and cured his patient. *Cheselden* a short time after gave the same advice.

II. *Duphenix* adopted a mode somewhat different. He made use of a long and narrow bistoury; plunged it in from above downwards and from before backwards; made it turn several times upon its axis in order to round off the opening which he had just made; introduced in its place a canula shaped like the point of a pen which was designed to conduct the saliva into the mouth, and the outer extremity of which, concealed in the cheek, was made to correspond with the parotid opening of the fistula. The borders of the ulcer were then excised, and in order to shut it up *Duphenix* immediately had recourse to the twisted suture. The canula left to itself came away on the sixteenth day, and the cure was thus accomplished.

III. According to *Monro* the cautery of *Deroy* and the bistoury of *Duphenix* are advantageously replaced by a shoemaker's awl. By means of this instrument, which the celebrated surgeon of Edinburgh appeared to have a great regard for, he traversed the cheek in the natural direction of the canal and contented himself, for a seton, with a thread passed into the wound. When its track was thereby rendered callous he removed this thread, ascertained that the saliva ran into the mouth, and then paid attention to the small external ulcer.

IV. *Platner*, who was a warm advocate of this mode of operating, recommends that the patient should be made to use a gargle of

brandy, in order to accelerate the induration of the internal orifice of the new duct, and that we should at the same time compress the wound on the exterior or touch it with the nitrate of silver.

V. J. L. Petit, after having traversed the parts, recommends that we should enlarge the buccal opening of the perforation by daily introducing into it a small piece of sponge until the fistula is closed up.

VI. *Tessart* as soon as he had passed a simple thread through the cheek perceived that the saliva flowed into the mouth. The use of a few strips of adhesive plaster proved sufficient to close up the ulcer promptly.

VII. *Flajani* recommends that we should pass a double silk thread through the fistula by means of a needle, and that in other respects we should proceed after the manner of *Monro*.

VIII. *Desault*, in a patient who could not support compression, made use of a hydrocele trochar to pass the thread through the cheek, fastened a meche to the internal extremity of this thread, and drew it from the mouth to the bottom of the fistula, in such manner, however, as not to interfere with the cicatrization. Withdrawn and replaced each day of a little larger size, the meche was abandoned some few days before the thread which supported it, and when the wound had become almost entirely closed.

IX. *Bilguer* like *Desault* had recourse to the trochar; but in place of the seton he left a leaden canula permanently in the inner half of the wound, which he closed up outside.

X. *Richter* placed in the mouth a piece of cork in order to support and receive the point of the trochar; made use of a seton of thread, the size of which was gradually increased; withdrew it when the new canal was sufficiently solid; afterwards cauterized the exterior wound or scarified it, and then reunited its borders. In the most obstinate cases he introduced through the mouth into the artificial duct, and left there permanently, a gold or silver canula provided with a head, in order to prevent its falling out.

XI. *M. Atti* more recently, in 1824, intending to improve upon the process called *Béclard's*, has on the other hand, rather modified that of *Desault*. By means of the canula of a small trochar, he is enabled to conduct through the cheek a tent of lead, pierced on its sides with several holes, supported externally by a thread which keeps it in the wound, and divided to the extent of about a line at its internal extremity into three branches, which being bent in the mouth, hinder it from being drawn upon by the thread. When the fistula is sufficiently reduced, *M. Atti* touches it with the lapis infernalis, after having removed the thread, or even endeavors to close it up entirely. The leaden tent abandoned in the cheek leaves behind it, in escaping into the mouth, at the expiration of a certain time, a new canal, which perfectly replaces the old one. The successful results which the author brings to the support of his method confirm in fact its value, and his process is without contradiction one of the most certain that can be imagined.

XII.—It is for example assuredly preferable to that of *M. Ch. Bell*, who like *Flajani* passes a needle through the cheek in order to introduce a thread and afterwards a seton into the fistula; and who,

when the internal opening of the wound has become callous, fastens a hair or very fine thread to the external extremity of the first thread, and afterwards proceeds in the manner of Desault and Bilguer.

G. *Internal tent*.—Since the last thirty years, surgeons with the hope of rendering the operation more prompt, and of being enabled to unite the wound by first intention, have turned their attention into another direction.

I. *M. Langenbeck*, rejecting every kind of foreign body, has proposed to dissect and to isolate the posterior extremity of Stenon's duct, then to make at the bottom of the fistula an opening which would allow of its being conducted into the mouth, and in order to fix it in its new relations to unite immediately the borders of the wound. But I am not aware that this professor has up to the present time had any imitators, nor should he have any in future.

II. *M. Latta* says that the best mode of curing salivary fistulas, consists in passing a catgut through the cheek, after which we should endeavor to introduce its external extremity in the parotid duct, leaving the other in the mouth, and closing up the wound accurately, either by the suture or adhesive plasters; as if it were a thing that was always possible to find the orifice of Stenon's duct at the bottom of an ulcer! *Zang*, however, eulogizes this mode of operating, when the fistula is very large, and the anterior portion of the canal shut up. Only he recommends that we should make use of the canula of the trochar for the purpose of conducting the catgut, that this latter should be shaped into a point at the extremity, which is to penetrate in the direction of the parotid, and in order that the saliva may run along its sides, that it should be made so as not to fill up exactly the artificial canal.

III. In reducing the practice of Latta and Zang to its true value it is immediately perceived that it differs from that of Desault or Ch. Bell, or that of *Vedrine*, (*Journ. de Desault*, t. IV., p. 294,) which latter traversed the bottom of the wound with a carlet needle, (*aiguille en carlet*,) only in the fact that they dispensed with retaining their tent outside by the aid of a foreign body; which enabled them to close up the fistula immediately, and to do this, whether they succeeded or not in placing one end of the catgut in the natural duct of the gland. It is, however, possible that we may cure by this mode, as by most of the processes which have been pointed out above; but it has the disadvantage of not holding the seton sufficiently secure in the thickness of the cheek, and of enabling it to escape too soon.

IV. The same objection may also be made to *Percy*, who on his part states that he had often succeeded by making use of a leaden sound, instead of the catgut which the Germans employ. Without claiming any pretension to it, *M. de Guise*, (*Bull. de la Fac. de Méd.*, 7 année, p. 40—44,) proceeded in the following manner in a young patient in whom the fistula, which had already existed a long time, had resisted a greatest variety of means resorted to. A hydrocele trochar inserted through the wound from without inwards, and from before backwards, enabled him to introduce into the mouth a leaden wire through the canula of this instrument. By means of a second puncture in the direction of the natural canal, that is to say, from

behind forwards and always from without inwards, he was also enabled to bring the other extremity of the metallic wire into the buccal cavity, reverse its two portions upon the inner surface of the cheek, and then unite the exterior wound by means of the twisted suture. At the expiration of a few days the agglutination appeared complete. The leaden noose, whose convexity corresponded to the fistula, and which included in its concavity the internal tissues of the cheek, was cautiously withdrawn, and from that time the cure was no longer doubtful.

V. Three observations related under the name of Bécclard, prove that this surgeon frequently imitated M. de Guise with success. In place of leaving the two extremities of the leaden wire free in the mouth, he united them and twisted them upon themselves, with the view of gradually cutting through the intervening tissues, as in fistula in ano. Moreover, in order to make the second puncture, he introduced the trochar through the mouth, in order that the beak of the canula might not prevent its being withdrawn through the same track after having adjusted the other extremity of the tent; which is not practicable when it is passed from the exterior to the interior, as it is the first time.

VI. *M. Grosserio*, finding that it was not as easy to pass the trochar through the mouth as it was through the wound, and desirous of remedying the inconvenience pointed out by Bécclard, has recommended a trochar provided with a canula which is wholly devoid of any shoulder. By means of this modification we withdraw it with full as much facility through the mouth in the second stage of the operation as through the wound in the first stage.

VII. Finally, *M. Mirault*, who has since recommended the same course, considers that a meche of thread would be preferable to a leaden wire, and that by means of a knot-tightener, made like that of Desault, we would more speedily accomplish our object than by simple torsion.

VIII. *M. Roux*, (*Journ. Heb.*, t. II., p. 178,) governed by the same idea as *M. Mirault*, made use of a silk seton with entire success. Finally, *M. Vernhes*, (*Revue Méd.*, 1830, t. IV.,) has been no less successful with a gold wire, placed from above downwards, not transversely, as recommended by *M. de Guise*, and which he employed like Bécclard to cut through the intervening tissue by twisting it gradually upon itself.

IX. Perhaps also we might confine ourselves to perforating in any manner whatever the parotid duct posteriorly at a short distance from the fistulous orifice, and to establishing on the track which the saliva takes an internal fistula in order to be enabled to close that which is outside. But this process which I proposed in 1823, has not yet been put to the test, and the facts of Trecourt, (*Mem. de Chir.*, p. 71,) or of Charve, (*Lombard, Opusc. de Chir.*, p. 24,) which have reference to it, are not very conclusive. Like that of *M. de Guise* and all its modifications, moreover, it would be applicable only in cases where the wound of the duct has not approximated too near to the masseter muscle. Also, in order to determine the relative value of so many different methods, it would be necessary to exhibit all the modifications which salivary fistulas may present. In this

point of view there are none of them which may not have their advantages.

H. *Appreciation*.—Nevertheless, the portion of quill of Ravaton, (*Chir. d'Armée*, p. 571,) the seton, after the manner of Desault, or Ch. Bell, the leaden tent of M. Atti, or that of Percy, Latta, or Zang, are, all things being considered, the best, and ought to be preferred. To proceed in the manner of M. de Guise or Bécclard, in adopting the modification proposed by M. Grosserio, it would be requisite that the fistula should be sufficiently remote from the masseter muscle. Under such circumstances this method is the most certain, and unquestionably the best of all.

### § III.—*Sub-maxillary Gland.*

If it should happen as in instances which are on record, that a wound or ulcer in the sub-hyoid region has extended as far as the sub-maxillary gland, and remained fistulous as in the case of Muys, (*Obs. de Chir.* dec. 6, obs. 4, p. 341,) or that of Lecat, (*Suppl. à la Chir. d'Heister*, t. V., p. 214, in 8vo.) we should be obliged, in order to effect its cure, to make trial of all the methods which have been passed in review in treating of fistulas of the parotid gland. M. Larrey, (*Acad. Roy. de Méd.*, 27th March, 1827,) abraded its borders, applied the quilled suture and succeeded. If it was found impossible to dry up the source of an ulcer of this kind; if, moreover, the secreting organ itself was profoundly altered and threatened with a serious degeneration, extirpation, which Pouteau ventured to recommend for the parotid, would here be a last resource, which should not be neglected. Should, says Rossi, (*Méd. Operat.*, t. I., p. 258,) cauterization and compression not succeed in fistulas of the duct of Wharton, the sub-maxillary gland must be extirpated. M. Amussat, (*Acad. Roy. de Méd.*, 27th March, 1827,) who considers that he has performed this operation, states that he has every reason to be satisfied with it. We shall hereafter speak of the course that is to be adopted under such circumstances.

### ARTICLE VI.—RANULA, (Grenouillette.)

Ranula is a disease of little importance, and one which, as Boyer says, is not dangerous. It has, however, been seen on more than one occasion to compromise the life of the patient, and in all cases it is sufficiently annoying to induce us to devise some mode of relief. F. de Hilden speaks of one which filled the entire mouth; and Marchettis of another which was so large as to compress the carotid arteries and the trachea. Alix states that he operated upon one in a child, which was upon the point of producing suffocation, and Taillardant mentions another which was of so large a size that it prevented the patient from eating. A. Burns speaks of an adult man whom he saw in the practice of Cline, and whose respiration was so much interfered with by the presence of a ranula that he swooned away after having been attacked with violent convulsions. A man who came, in 1837, to the public consultation at the hospital of La Charité, had a ranula which, occupying the totality of the left parotid

and supra-hyoid regions, must have contained near a pound of fluid. I have seen two other cases in which the mouth was as it were filled up by them. Though the ancients were but imperfectly acquainted with the nature of this disease; though some make of it with Celsus an encysted tumor, and that others with Aetius ascribed it to a varicose dilatation of the sublingual veins, or with Abu'l Kasem to cancer, or with Paracelsus considered it to be an apostema of the vessels of the tongue, or with Aranzi an ordinary abscess; they nevertheless attempted its cure by almost all the different means employed since the time that Louis endeavored to prove that it is nothing else but a tumor produced by an accumulation of saliva, either in the maxillary gland itself, transformed into a cyst, or in its excretory duct, which has been enormously dilated. MM. P. Dubois and Stoltz (*Gaz. Méd.*, 1833, Novembre; *Journ. des Conn. Méd. Chir.*, t. I., p. 182.) have each given an example to prove that ranula is sometimes congenital, and that it may occupy the sublingual gland. In place of pure and limpid or inspissated saliva, mucus or purulent matter, or a viscous substance of more or less consistency, the diseased pouch is sometimes filled with gravel, sand, or even legitimate calculi. In a case related by Tulpius it was composed of a concretion so hard, that it became necessary to use the actual cautery in order to destroy it. Schultz, E. Koenig and V. Rieddin, mention facts of the same kind, which have also been met with by J. L. Petit, Freeman, Sabatier, Taillardaut, Loder and Boyer. M. Walther (*Revue Méd.*, 1826, t. II., p. 142.) asserts that he has, in two instances, found calculi in Wharton's duct. An analogous fact has been since published by M. Baker, (*New Amer. Archiv.*, &c., p. 249, July, 1835.) The diagnosis was clear in all these cases. An incision of sufficient extent upon the tumor allowed of the extraction of the foreign bodies, and the cure was speedily accomplished. Ranula, (grenouillette,) properly so called, requires other precautions. Experience has shown that, whether, after the example of La Faye, (*Journ. de Connais. Méd. Chir.*, t. I., p. 182,) we admit two species of it, one for the sublingual gland, and the other for Wharton's duct, or whether on this point we concur with the general doctrine, the evacuation of the liquid will not be found a sufficient preventive of a second obstruction. For the treatment of this disease, incision, caustics, tents, dilatation, excision, extirpation, permanent canulas, the seton, &c., have each in turn had their partisans.

### § I.

*Incision*, which first presents itself, immediately empties the tumor and appears to cure the disease. The organism, moreover, must have first suggested this idea, inasmuch as ranula very frequently bursts of itself. Hippocrates had already recommended it, and effected it by means of a lancet. Celsus and Aetius speak of it, but do not appear to have any great confidence in it, any more than Rhazes, who had his fears on this subject, from the vessels which the bistoury may at the same time wound. Abu'l Kasem, though somewhat bolder, did not venture to have recourse to it except for sublingual tumors that were of a whitish color and fluctuating, seeing

that by cutting into the others we incurred the risk of making them pass into a cancerous condition ; that is to say, that Abu'l Kasem had been led, without knowing it, to distinguish the legitimate grenouillette from the tumors with which it was in his time confounded. *Paracelsus*, in place of plunging the instrument into the cyst itself, confined himself to opening the vessels which go to it, and can scarcely therefore be considered among the number of partisans for the incision of ranula. When a fluctuation is perceived in it, *Aranzi*, who does not distinguish it from abscesses, recommends that it should be opened with the phlebotome, and P. Forrest says that it does not return if, after having incised it, the surgeon takes care to make pressure upon it, and to expel all its contents. According to Bartholin, *Six* waited until the inflammation in the tumor had ceased, when he pierced it through and through, in order to evacuate the contained matter. Jourdain, notwithstanding the arguments of V. D. Wiell, and the experience of every day, still maintained, about the middle of the last century, that a free incision by means of the lancet very frequently effected a cure of the grenouillette, and that we may confine ourselves to this remedy. There are, in fact, patients who have been in this manner permanently cured of their disease ; but all the world, at the present day, agree that this remedy is only palliative, and that in general the salivary cyst is not long in again becoming filled up.

## § II.—*Catheretics*, (cathérétiques.)—*Injections*.—*Tents*.

*Paracelsus*, in order to retain for the operation a part of its ancient simplicity, to prevent the wound from closing up too rapidly, and to effect in fact a cure which incision alone was far from always obtaining, maintained in the wound detergent substances ; *Purmann* introduced styptics into it and was successfully imitated by V. D. Wiell ; *Camper* touched it with the lapis infernalis, and *Acrel* left in it a roll of lint saturated with the spirit of salt ; while *Callisen* recommends that we should place in it *lint only* or cauterize its bottom with a mineral acid ; which causes, he says, the cyst to become detached and enables us to remove it. A surgeon of Saltzbourg, quoted by *Sprengel*, found it more convenient to inject into it camphorated *spirits* or essence of turpentine and cured his patient. It was the same with a patient mentioned by M. Haime, of Tours, (*Precis Méd. d'Indre et Loire*, 1821, 2nd trim.) and whom this physician cured by means of injections, thereby inducing the adhesion of the walls of the cyst. *Leclerc* had not been less fortunate with the *nitrate acid of mercury*, and the case of *Sabatier* proves that a tent of lint renewed or cleaned each day, suffices after the incision of the ranula to render the wound fistulous and to effect a radical cure. Nevertheless, as it not unfrequently happens that the disease resists all this combination of remedies, it has been proposed to destroy a portion of the sac of which it is constituted. I am in truth surprised that no one up to the present time has applied to salivary tumors the puncture and irritating injections used in hydrocele. Everything, for example, induces us to believe that iodine injections would prove successful.

§ III.—*Cauterization.*

Caustics were employed at the time of Aetius. Dionis gave the preference to a mixture of sulphuric acid and honey, but the hot iron has found a greater number of partisans than escharotics, properly so called. These last, in fact, are less easily managed, less sure in their action, and almost always dangerous when applied upon so delicate a region as the mouth. *Paré*, who had fully experienced the inconveniences of this remedy, proposed to plunge into the tumor a species of trochar heated to a white heat, passing it through a metallic plate destined to protect the surrounding parts. In this manner he obtained a loss of substance, the wound remained fistulous, and the *grenouillette* did not return. *F. ab Aquapendente* passed his cautery through a perforated canula. *Louis* gives nearly the same advice, that is to say, he prefers the actual cautery to the cutting instrument; only he makes the remark that by placing the opening of the cyst in front, we incur the risk of seeing the saliva issue out and escape involuntarily from the mouth. Nevertheless cauterization is rarely employed at the present time, as much perhaps because of the fear that it occasions to the patient as owing to its not being always infallible. *M. Larrey*, (*Clin. Chir.*, t. II., p. 48,) who recommends that the incandescent cautery should perforate the tumor through and through, is almost the only person, with the exception of *M. Pl. Portal*, (*Gaz. Méd.*, 1834, p. 540,) who continues to give it the preference.

§ IV.—*Excision.*

*Tulpius*, *J. L. Petit*, *Desault* and *Richter*, desirous of systematizing the process of *La Cerlata*, who hooked up the ranula with an erigne and excised it with a razor, or that of *F. ab Aquapendente*, who seized it with the forceps and divided it with the scissors or applied the ligature to it, have endeavored to prove that by removing a flap of sufficiently large size from the cyst, the tumor is scarcely ever reproduced. The fact is, that in his practice at the *Hotel Dieu*, *Desault* almost always succeeded by this method, one which *M. Coley* (*The Lancet*, 1828, vol. II., p. 495), states that he had had every reason to be satisfied with, and which *Boyer*, who never practised otherwise, had the highest opinion of. It is the method adopted by *M. Graefe*, (*Revue Medical.*, 1830, p. 143,) who in this manner removes half of the cyst. It is moreover performed in various ways. The most simple and surest mode is the following: the jaws of the patient being separated as much as possible, the surgeon provided with a straight bistoury commences by making a semilunar incision with its convexity outwards, upon almost the entire surface of the tumor facing the gums; he then seizes with a good pair of dissecting forceps the flap thus cut, and detaches it by means of the scissors while giving it an elliptical form. In general no vessel of any importance is wounded. It is rare that there are more than a few drops of blood or that the patient experiences any pain. Dressings are useless, and the wound which diminishes from day to day without however entirely closing, prevents any return of the disease, at least in most cases.

§ V.—*Dilatation.*

Though the disease in general is owing to the course of the saliva being interrupted, and though Louis, (*Mém. de l'Acad. de Chir.*, t. IX.) imitated by Leclerc, may have succeeded in clearing out the orifices of Wharton's ducts, which seemed like two aphthæ on the sides of the frenum, and that he has been enabled to dilate them by placing a sound in them, and that the patients thus treated have recovered; it must nevertheless be conceded with Richter, that dilatation in such cases would be a most uncertain resource, one that was exceedingly difficult, and often even wholly impracticable. Excision after the manner of Boyer has undoubtedly immense advantages over it, without exposing to the same manipulations and difficulties.

§ VI.—*Permanent Canula.*

This has not prevented some modern operators from pronouncing in favor of incision, which they have thought could be made more efficacious by combining it with the employment of a canula left permanently in the opening of the cyst. The idea of a combination of this kind had not been mooted before the time of Sabatier, though this author himself speaks only of a canula left in the wound a sufficiently long time to render it callous. But in his time it had evidently suggested itself to the minds of some other practitioners, inasmuch as he speaks of a patient who had worn one for three years, and whom he recommended to keep it in still longer. This instrument, which was about an inch long, and having on one of its extremities a lenticular button, which prevented it from penetrating too far forward, did not produce any serious inconvenience, either to the speech or mastication of the person who wore it. Lecat (*Richard de Hautsierck*, t. I., p. 403, pl. 408) cured a patient of *grenouillette* by means of a short canula contracted in its middle, and terminating in a shoulder on one extremity, and like the spout of a watering pot at the other. This is the canula that Dupuytren (*Bull. de la Fac. de Méd.*, t. VII., p. 65) has modified in an ingenious manner, by making it still shorter, and terminating it by a lenticular plate at its two extremities. This professor, after having opened and emptied the cyst, inserted into it one of the extremities of his instrument, while the other remained in the mouth. The tissues which embrace its neck, soon become sufficiently contracted to prevent its becoming afterwards displaced either in one direction or the other. The saliva escapes through its canal, and the patients keep it in as long as is judged proper, sometimes even during their whole lives, without being in reality incommoded by it. Dupuytren recommends that the buttons of his canula should be of gold, silver, or platina, and that they should be convex on their free surface only, and concave within, in order that the food may not become caught between them and the walls of the cyst. There is no objection in fact to making trial of this method, which, according to the editors of Sabatier, succeeded constantly at the Hôtel Dieu. But I do not perceive in fact that it possesses any particular advantage over simple excision, which, on

the other hand, was rarely attended with failure in the hands of Boyer.

### § VII.—*Seton.*

It is seen from this review that the treatment of *grenouillette* is entirely based upon that of hydrocele, as M. Haine has likewise remarked, and also Purmann, who had already endeavored to effect adhesive inflammation of the salivary cyst in the same manner as we do adhesive inflammation of the tunica vaginalis. There remains the seton, which might be employed with some prospect of success, if the other method were not infinitely more rational. This resource, however, possesses a certain degree of efficacy, as is proved by the practise of Physick, (Dorsey's *Elements of Surgery*,) who was long in the habit of employing it, also by the observations of M. Lloyd, (*Lancet*, 1828, vol. II., p. 495,) who also made use of it at London, and the memoir published by M. Laugier, (*Journ. Hebdom.*, t. III., p. 9.) The presence, moreover, of a *foreign body* of the smallest size in the salivary ducts, is sufficient to produce accidents of quite a serious character. We have seen above, that saline concretions and various kinds of calculi sometimes form in these organs. A disease of the mouth, which resisted every treatment, disappeared after the extraction of a fish bone, which had got introduced into Stenon's duct, (*Revue Méd.*, 1831, t. II., p. 373.) A similar thing took place in a shoemaker mentioned by M. Robert, (*Ibid.*, t. II., p. 374,) who had a hog's bristle in Wharton's duct. A piece of straw, which had entered into this canal, caused various accidents there, and abscesses which were not cured until after the expulsion of the foreign body, (*Gaz. Méd.*, 1838, p. 793.)

### § VIII.—*Extirpation.*

Loder and Sabatier have seen the disease resist these different modes of treatment, and many authors had already contended that the surest mode is to extirpate the *grenouillette* or to destroy it entire by means of caustics. Celsus, in a rather obscure passage in his works, would lead us to believe that he himself was acquainted with this extreme remedy. Treating of sublingual tumors, he recommends when they do not yield to puncture, that we should incise the skin that covers them, in order to extract them, taking care not to wound the vessels, while an assistant separates the lips of the wound. Mercurialis, the first author who distinctly recommended it, raises up the tumor with an erigne, cuts it at its base in the mouth, and says if we do not destroy the whole cyst, the disease is sure to return. Diemerbroeck commenced by making a crucial incision into it, and then extirpated the whole of it. Alix, without going as far as this, incised it largely, but lengthwise, and then removed as much of the cyst as he could by means of the scissors. Marchettis, who in a very severe case had introduced a meche as far as into the mouth, by penetrating through the supra-hyoid region, was, nevertheless, obliged to extirpate as much of the tumor as he could, and to destroy the rest with a hot iron. It appears, nevertheless, that complete extirpation was but rarely performed by these different

practitioners. It scarcely ever becomes indispensable unless the evil should threaten to take on a serious degenerescence, or to be transformed into a solid tumor. Otherwise, all that is actually necessary is, to excise the portion which projects into the mouth; so much the more so, because by then touching the bottom of the wound somewhat actively with the nitrate of silver, its exfoliation is readily accomplished. An enormous cyst occupied the entire supra-hyoid region; M. Malcolmson (*Gaz. Méd.*, 1838, p. 743,) excised an ellipse from it, and the gland was seen at the bottom; he then excised this, and extirpated it nearly entire, when the patient recovered; but I am not satisfied that the lymphatic ganglions may not have here constituted the great bulk of the disease removed.

#### ARTICLE VII.—TUMORS OF THE MOUTH.

Tumors that are salivary, at least in appearance, are sometimes encountered elsewhere than on the sides of the tongue. I treated at the Hospital St. Antoine, a patient who had had one of these for a long time, between the lip and the left superior alveolar arcade, and who procured relief every month by plunging into it a bistoury or a lancet. M. Graefe states that he has often met with them in the substance of the lips. Wilmer mentions one, which was situated in the lower jaw; and Dupuytren, as well as Runge, (*Thèse de Haller*, t. I., French translation,) have frequently seen them in the substance even of the bones. The one which M. Latour, (*Arch. Gén. de Méd.*, t. VIII., p. 52,) had under treatment, occupied a large portion of the cheek, and M. Ricord, (*Ibid.*, t. VIII., p. 527,) has published under the title of hydatid of the canine fossa, a case which probably belongs to the same kind of lesion. All the processes above pointed out are applicable to these tumors; but when we are desirous of obtaining a radical cure, it is advisable to have recourse to simple excision, conjoined with cauterization, or to extirpation. These tumors, filled with a viscous yellowish or transparent liquid, are not rare. I have seen them in the tissues of the cheeks and lips, between the gums and cheek, as well as between the gums and tongue, and without any communication whatever with the salivary ducts or glands. M. A. Bérard, (*Arch. Gén. de Méd.*, ser. III., t. I., p. 402,) extirpated one which was of the size of an egg. A concrete tumor was situated between the tongue and the jaw; to remove it entire with greater facility, M. Roux, (*Mercier et Vigla, Journ. des Conn. Méd. Chir.*, t. IV., p. 104,) divided the lip vertically and found it necessary to saw through the inferior maxillary bone on the median line. It became necessary to await the exfoliation of some splinters, but the operation was followed with entire success. The wounding of the salivary ducts may also give rise to tumors of this description, even upon the track of Stenon's duct. M. Verhnes has published an interesting case of this kind, which must be classed with that of M. D. Lasserve; in consequence of a traumatic lesion, there formed upon the inside of the cheek a small oblong tumor filled with saliva, and which M. Verhnes succeeded in curing by passing through it a small trochar, attached to which was a double gold wire, which he employed in the manner of a seton. If a case of this kind should again present itself

the method of this surgeon ought to be adopted, unless we should prefer to confine ourselves merely to the process of Bécclard for salivary fistulas, or to the treatment of grenouillette.

## ARTICLE VIII.—THE TONGUE.

### § I.—Operation for Filet, (Tongue-tie.)

The species of fibro-mucous fold which attaches the free portion of the tongue to the posterior surface of the chin, and which is called *frenum* when its dimensions are properly proportioned, takes the name of *Filet*, when it is too long from before backwards, or too short from above downwards. It then becomes impossible for the infant to suck. The point of the tongue being then arrested against the lower wall of the mouth, renders it impossible to draw it outwardly, in order to seize the nipple. This is an arrangement, therefore, which might be attended with serious consequences, if we did not immediately attend to its removal. Only that we should be careful not to suppose that the infant is tongue-tied as soon as it does not suck, or is a long while in beginning to talk. Such accidents, which a thousand different causes may occasion, do not depend upon the frenum of the tongue, unless it be found that when the finger is passed into the mouth, it is impossible to be seized hold of by it, or that its point cannot reach as far as on the lips, in which cases only we should undertake the section of the filet.

A. There is nothing to show, unless it be a remark in Cicero, that this small operation had been described *before the time of Celsus*, who, in order to perform it, recommends that we should raise the tongue with the forceps, and already at that period advises that we should be careful not to divide its vessels. Paul of Egina and Abu'l Kasem employed a hook in place of the forceps. Avicenna, in order to be more certain to avoid any hemorrhage, passed a ligature through the base of the frenum, and in this manner dispensed with the cutting instrument. De la Cerlata, who censures midwives for tearing out the filet or dividing it with their nail, destroyed it by means of a particular instrument, and raised up the tongue with his two fingers.

The sharp-pointed scissors of Friederich are justly condemned by Fabricius ab Aquapendente, who severely censures the pernicious practice of midwives, already pointed out by De la Cerlata, and moreover remarks that this operation is rarely required. F. de Hilden is of the same opinion, and performed the operation with a cleft instrument, which served at the same time as a scissors and as a fourchette to raise up the tongue. The instrument of M. Montain (*Mém. de Therap.*, 1836, p. 34,) is nothing more than an improvement of that of F. de Hilden. The blunt fourchette and the large scissors devised by Scultetus and Solingen are useless. The idea of cutting the filet with a bistoury heated to a white heat, as was practised by Lanfranc, would at the present day be considered absurd. The spring instrument of J. L. Petit, and which was eulogized by Platner, appeared to be attended with too much inconvenience in the opinion of Le Dran, who maintains that the blunt-pointed

scissors will always answer, and that it is unnecessary to go to the extent of Dionis, by lacerating the wound with the finger, in order to enlarge it after the incision is made. The cleft spatula of Richter and Callisen, and the curved and blunt-pointed scissors invented by G. Schmitt, are not in use with us at the present day, though in fact they might be made to effect the object intended by their authors. M. Colombat, who is always ingenious in constructing new instruments, has proposed one, which appears to me altogether useless, as does also the excision which he recommends to be substituted in place of the simple incision.

**B. Operative Process.**—We adopt the method of Le Dran, that is to say, the infant being seated and its head held back by its nurse, or some other person who will not be disturbed by its cries, the surgeon raises up its tongue by means of one or two of the fingers of his left hand, while with the other hand holding a blunt-pointed scissors, he rapidly divides the frenum. But, inasmuch as the size of the fingers may frequently embarrass the remainder of the operation, we have generally made use, since the time of J. L. Petit, of a canulated sound, the cleft plate of which being substituted in their place, protects at the same time the vessels. When the filet is properly secured in the bifurcation of this plate, the operator slightly raises up its handle towards the forehead of the child, in order to push the tongue backwards and upwards. Then introducing the scissors underneath, he divides with a single cut the small membrane thus stretched, taking care to direct the point of the instrument slightly downwards, in order to be sure that he runs no risk of wounding the ranine arteries. The wound requires no precaution, and it is extremely rare that the little patient suffers any pain from it beyond a few hours. The movements of the organ prevent its reagglutination, and I am not aware that there is any necessity in this matter to touch it with nitrate of silver, as is recommended by M. Hervez de Chegoïn.

**C. Accidents.**—*Tetanus*, which was produced by the section of the filet, in the child mentioned by J. Fabricius, and which operation had been performed by a charlatan, has never been observed since. According to some authors, two serious accidents, *hemorrhage* and *reversion of the tongue* into the pharynx, may however be caused by this operation. The first happened to Roonhuysen, who could not arrest the blood until he had applied vitriol to the bottom of the wound. Maurain incurred still greater dangers, and was obliged to come to the actual cautery. J. L. Petit mentions two cases in which the operation having been badly performed, the patients would have evidently succumbed if he had not immediately afforded them relief. A circumstance which in these cases aggravates the danger is this, that the blood in place of being spit out, is swallowed in proportion as it flows, and that if we are not vigilant the child may die before we have suspected the cause.

I. If we employ the sound, and take the precaution to incise nearer the inferior wall of the mouth than to the tongue, it is next to impossible that such a hemorrhage can take place. If it should happen, however, it may be stopped by directing upon the point which bleeds the head of a probe heated to a white heat. J. L. Petit suc-

ceeded by means of a wooden fork an inch long protected by linen, and having its point d'appui against the inner side of the maxillary symphysis on the one part, on the other embracing the top of the wound, while a small band passed transversely in the mouth, then brought out and crossed under the jaw, and raised up above the ears to be fastened to the child's cap, hindered the tongue from moving. Two stems united in any manner whatever at their middle portion so as to form a forceps, by means of which the bleeding part should be seized, and which should be made to act by pushing a wedge between the two halves of its other extremity, would bring about the same object, and in fact attain it with still more certainty. The natural softness of the tissues, and the retraction of the arteries, would in general render the ligature recommended by Courtois wholly inapplicable.

II. As to the *reversion* of the tongue, the moderns have with difficulty admitted its possibility. J. L. Petit, who has seen three examples of it, explains it in saying that the frenum having been divided the tongue becomes free, is raised up and directed towards the windpipe with so much the more facility, because the infant, who, up to that time had not been able to seize hold of the nipple, now sucks upon it with a degree of voracity. In one case, this practitioner had three times to draw back the tongue out of the pharynx, but the fourth time the patient died notwithstanding. J. L. Petit has *seen* the reversion in question during life, and has *demonstrated* its existence after death. It is therefore an unquestionable fact. Nor can I see why it should be so difficult to comprehend, nor why we should call in doubt what travellers have said of those Eastern or African people, who, in order to escape severe punishments, killed themselves by *swallowing* their tongue. Any person may ascertain upon himself, that the tongue can be reversed to the upper part of the pharynx, and that there would be no very great difficulty in closing with it the posterior opening of the nasal fossæ. A similar fact to those of Petit, has moreover been related since by M. Cross, (*Presse Méd.*, t. I., p. 388.) We avoid this reversion by not dividing the filet too deeply. In order to remedy it we must bring back the tongue by means of the finger into its natural position, make the infant constantly suck so long as there is danger, and when it does not suck, keep its mouth carefully shut.

#### § II.—*Anchyloglossis, (Adhesions of the Tongue.)*

Adhesions of the tongue have at every epoch attracted the attention of surgeons. Whether they be congenital or acquired, the result of simple inflammation or the product of more deep-seated lesions, ancient or recent, the cutting instrument is nevertheless the only resource for their relief. Aetius says that the abnormal membrane, or cicatrix, is to be seized with a hook, and to be then divided with the necessary precautions. J. Hellwig, having been consulted by an individual who could not articulate sounds, destroyed by dissection the adhesions of his tongue, and thus restored his speech. At the present day, we proceed in the same way. Only it is important that we should not allow ourselves to be imposed upon by an ar-

rangement that is sometimes met with in new-born infants. In such cases their tongue is merely glued (*collée*) either against the vault of the palate, as Louis has seen it, or to the lower wall of the mouth, which has caused more than one old grandmother to suppose that the child had no tongue. The finger, the handle of a scalpel, or the spatula, will be found sufficient to destroy this simple agglutination, which in fact is nothing more perhaps than the beginning of a true anchyloglossis. The method to be adopted would be still the same in an adult, if we should be called before the adhesions, which have been the result of a diffused inflammation, have acquired a certain degree of solidity.

A. If there should be only a few *bridles of slight extent* upon the sides of the frenum, we should divide them with the scissors, like the filet, and with the same precautions. We should divide in the same manner those which are not unfrequently found to have been formed between the cheeks and borders of the tongue, in consequence of mercurial gastritis and other phlegmasias of the mouth, examples of which have been communicated to the Academy by MM. Duval, Cullerier, and Bernard. Should they have a certain degree of breadth, they should be excised in place of simply dividing them. After having detached them from the buccal wall by one cut of the scissors, we should seize them near the tongue, in order to remove them by a second cut with the same instrument. We may also remove them by embracing them successively at their middle portion with the forceps, while we detach their borders with the scissors or bistoury.

B. When on the contrary these *adhesions* are close, or cellular, as it is termed, the dissection must be conducted with more particularity and caution. The surgeon being placed behind, and to the right of the patient, whose head is held back upon a pillow, the arm of the nurse, or against the chest of an assistant, endeavors to separate by means of the left forefinger, a spatula, or a portion of a sound, or any other suitable instrument, the free portion of the tongue from the point in the mouth which keeps it immovable. Dividing gradually with a straight bistoury held flatwise, all the lamellæ or unnatural attachments which he intends to destroy, and not forgetting, at the inferior region especially, slightly to incline the edge of his instrument towards the wall of the mouth, or to remove it as far as the state of the parts will permit from the body of the tongue itself, in order to avoid the vessels with greater certainty, he sponges up the blood in proportion as it runs out and stops from time to time, in order to afford the patient time to breathe and to have his mouth cleansed out. He then cauterizes with a hot iron if any hemorrhage exist, or in other cases prescribes some styptic or astringent lotions, and finishes by pressing his finger upon all the points of the wound in order to assure himself that there no longer exists any improper adhesion. Emollient gargles, extended and frequent movements of the tongue, and the precaution of frequently gliding the finger between the divided surfaces in order to prevent their reunion, are all that remains to be done until the cure is completed, which is usually accomplished from the fifth to the thirtieth day, but which requires all these attentions in order to be effected with certainty.

§ III.—*Tumors and Ablation of the Tongue.*

A. *Gangrene, induration, fungous* and schirrous tumors, cancerous ulcers and true *cancers*, are the principal diseases which may require amputation of the tongue either entire or in part. It is an operation which has been only lately introduced into practice. Deterred by the idea that the tongue is the exclusive organ of speech, although J. Lange asserts that he had already often removed it in consequence of gangrene, this operation was thought of only with dread, when Louis demonstrated that many individuals, though deprived of a large portion of this organ, nevertheless continued to have their speech and to distinguish the taste of different substances. The laborer mentioned by Roland de Saumur, and who had lost his tongue down to the root in consequence of gangrene, could speak, spit, swallow without difficulty, and taste different substances.

The young girl noticed at Lisbon, by De Jussieu; the Margaret Cutting mentioned in the Philosophical Transactions; the Marie Gulard referred to by Bonami and Louis; the girl, A. M. Federlin, whose history is published by Auran; the young man whose tongue was torn out by the corsairs because he would not be made a Musulman, and whom Zulpinus states he saw, and another person who had his tongue cut out by robbers, and whom Zacchias mentions to have seen, were cases of this description. It is also known that in Germany, Italy, Spain, &c., it has a long time been the practice to punish malefactors by cutting out their tongue but most of whom, notwithstanding, have retained the faculty of speech. All the world in fact are familiar with the two cases so quaintly described by A. Paré: 1st, of a mower, who after having been mute for the space of three years in consequence of having lost a portion of his tongue, being ridiculed by one of his comrades while he was holding a wooden vessel between his teeth, made an effort and uttered, to his great astonishment, a few words, and who, taking advantage of this circumstance, finally learned to speak distinctly by means of a saucer or small cup; 2d, of a young boy whose tongue had been cut off, and who recovered his speech by making use of the instrument invented by the preceding person. Though it be satisfactorily proved that the loss of the tongue does not always involve complete loss of speech, it is nevertheless true that its amputation has been more than once performed without any very evident necessity. We should dispense with it for example at the present day, and would not imitate Pimpernelle, (Bonet, *Corps de Méd.*, t. IV., p. 305.) even though the organ had become so much swollen as to protrude outside, unless it was accompanied at the same time with an actual schirrous or cancerous degenerescence. Serous cysts, abscesses and collections of blood might be laid open or excised without the necessity of extirpating the tongue. In a case cited by Thymæus, (*Ibid.*, t. III., p. 201.) and in another for which we are indebted to Bonavert, (*Trans. Philos. Abreg.*, t. IV., p. 340.) a tumor upon the tongue contained a *stone* of the size of an almond. A patient of Sedelius (Bonet, *Corps de Méd.*, t. IV., p. 62) presented the same phenomenon. Dumonceau (*Mém. de l'Acad. de Berlin*, t. VII., Append., p. 130) mentions that a retention of urine was not removed until after

the extraction of a stone which was found under the tongue, and we see also in a case of Leautaud (*Ibid.*) that a similar calculus had produced fever with an abundant salivation. In all cases of this kind we should never think of amputation of the tongue. It is an operation therefore which in the main must be reserved for cancerous tumors, and other degenerescences of bad character.

B. *Operative Process.*—The operation, moreover, is performed in quite a variety of modes, and should be modified in fact according as the disease presents itself on this or that part of the organ.

I. *Process of Faure.*—The erigne forceps or scissors curved flat-wise, will answer for the excision of *pediculated tumors* of greater or less size, and which rarely appear upon the tongue except on its dorsal surface. The ligature would not have the same advantage, and however little of the disease we may apprehend to have left behind, it is important, in addition, to cauterize the bottom of the wound with a hot iron.

II. If the alteration should be confined to the tegumentary layer, it would be necessary, as Walée, after the manner of Bartholin, appears to have done long since, to remove only the degenerated lamellæ and to preserve the muscular tissue.

III. Should the *chancrous ulcer* be deeper and situated upon the borders of the tongue, we should then, in order to destroy it, no longer make use of the curved bistoury, as was done by a surgeon made mention of by Ruysch. The point of the tongue being wrapped in a dry piece of linen, is drawn to the outside by the hand of an assistant, who inclines it towards the side opposite to that of the disease. The operator, provided with a straight bistoury, commences by making an incision of several lines in extent on the lower surface and throughout the whole length of the organ; makes another on its dorsal surface; thus encircles the cancer, including with it a certain extent also of the sound parts; then secures it with the forceps or erigne, and promptly completes its excision. The actual cautery, without being really necessary, becomes a matter of importance at the termination of the operation, as in the preceding case. If, out of the three persons operated upon in this manner by M. Heyfelder, (*Journ. des Conn. Méd.*, t. II., p. 347,) a cure was effected only in one, it was certainly not the cautery which did it.

IV. *Ligature.*—When the *disorganization is still deeper*, when especially it has extended very far backwards, and that it, nevertheless, appears to be practicable to preserve one of the halves of the tongue, we may have recourse to the *ligature*. It would protect us with more certainty against hemorrhage than the bistoury, and nothing prevents us, if we apply it in a particular way, to go back with it nearly as far as the larynx. A tumor of a doubtful character, which was situated upon the side of the tongue and which was tied at the supra-hyoid region, and also at the mouth, was in this manner ultimately detached, resulting in the recovery of the patient, (Arnolt, *Gaz. Méd.*, 1839, p. 106.)

a. *Process of M. Mayor.*—The organ is first transfixed through the mouth, and at its most remote part, from below upwards and from before backwards, by a strong bistoury, which being brought forward divides its whole length into two equal parts without touch-

ing the neighboring arteries. The operator then adjusts, at a point beyond the disease and upon the affected portion, the noose of a strong ligature of thread, the two ends of which he passes separately through a metallic tube, of a square shape and pierced with two openings slightly convergent, then through the other pieces of the chaplet knot-tightener which I have spoken of in the chapter on ligature en masse; thus embracing the base of the flap which is to be destroyed, he turns the small winch, and when the constriction is carried as far as is desired he attaches the free portion of this apparatus to the labial commissure, either by means of a thread or a small band. The pressure is increased in the same manner daily, and even several times during the day. The tissues soon mortify, and either separate or may be excised without danger on the third or fourth day. The knot-tightener of M. Mayor, which has been employed in five instances with success by its inventor, and which is a real improvement upon the instrument devised by MM. Bouchet and Braun, has the advantage in consequence of its flexibility of adapting itself without difficulty to the inequalities of the tongue, of occasioning but very little inconvenience in the interior of the mouth, and of allowing of a constriction which is at the same time moderate, energetic, and permanent. Should it not be at hand, however, the knot-tightener of Desault or that of Levret might, in these cases, be employed here with full as much advantage as for the ligature of polypi in general.

b. If the *whole breadth of the tongue* is diseased, either at its point only or as far down nearly as its base, the ligature would still be applicable. The proof of this is demonstrated in the observations of La Motte and Godard, each in a different case. Ev. Home and Mirault (*Soc. de Méd. de Montpellier*, t. IV., p. 517,) passed a double ligature through the centre of the tongue and brought its two halves out, to be knotted upon the sides of the organ, which they succeeded in this manner in dividing and separating by suppuration. M. Galenzowski (*Journ. de Progrès*, 2e série. t. I., p. 256,) in order to destroy a fungus hematodes which occupied one of the sides of the tongue employed a triple ligature and succeeded. In place of previously slitting through the tongue from before backwards, as is recommended by M. Mayor, M. Maingault (*Journ. de Prog.*, t. XIV., p. 511, 1re série,) proposes that we should apply the ligature by the mouth and pass it through each half of the tongue on its side, by means of the curved needle of Deschamps, which certainly would be preferable if it were possible to go far enough back.

c. *By the supra-hyoid region.*—I have elsewhere described, (*Arch. Gen. de Méd.*, 2e sér., t. V., p. 638,) after having seen the operation made trial of by M. J. Cloquet, another process, since improved by M. Mirault, the son, (*Mém. de l'Acad. Roy. de Méd.*, Paris, 1835, t. IV., p. 35.) An incision between the os hyoides and the chin enables us to introduce in this manner, from below upwards and from before backwards, through the base of the tongue, a double ligature which is to be turned one on either side, upon each half of the organ, in order to bring them out through the same opening below, and to fix them with a knot-tightener under the jaw.

V. So long as the *tumor does not extend too far backwards*, and

that it retains a small portion of sound tissues upon its borders, *excision* with the cutting instrument is preferable. *Louis* recommended, after the manner of the ancients, that after having hooked the tongue by means of an erigne forceps, or the forceps of *Museux* for example, we should amputate it by merely cutting through it simply and transversely with the bistoury.

VI. At the present time we adopt a much more rational process. The surgeon having seized the morbid mass with a strong erigne or hook forceps, draws it out of the mouth with one hand, circumscribes and removes it with the other by means of two cuts of the scissors, making a V incision through the sound parts, and the point of which faces backwards and is to fall upon the median line. Immediately approximating the two sides of the wound, they are to be united by three points of suture, one on the dorsal surface, a second at its point, and the third on its lower surface. The agglutination is often completed by the second day. The threads may be withdrawn on the third or fourth day, and the cure is generally completed from the eighth to the tenth. This is what has been seen to take place by *Boyer* and *M. Langenbeck*, and what I myself have witnessed. In this manner the deformity is reduced to as slight a degree as possible, and the accurate coaptation of the bleeding surfaces so frequently of itself arrests the hemorrhage that it becomes unnecessary to recur to any other hemostatic means.

VII. *Process of the Author*.—Whatever process may be preferred, a noose of thread passed through the point of the organ always simplifies the operation. By means of this noose the surgeon does with the tongue what he pleases; he draws it out, relaxes it, depresses or elevates it, and directs it to the right or to the left, without in any way interfering with the movement of the instruments. *M. Diffenbach*, (*Gaz. Méd.*, 1838, p. 808,) who employs two nooses of this description, passes them behind the tumor and not near the point of the organ. Since the year 1831 I have employed them in ten cases, and I cannot too highly recommend them to the use of practitioners. *M. Graefe* (*Bull. de Fér.*, t. XX., p. 211,) and *M. Delhay* (*Journ. Univers. Hebdom.*, t. IX., p. 20, 1832), have been equally well satisfied with them. If the tumor does not occupy the end of the tongue, and should it be found nearer the middle than the border of the tongue, after making use of this precaution, I hook the degenerate portion with an erigne in order to stretch it and encircle it in an ellipse by two semilunar incisions. Should it become necessary to remove one half of the organ, I first detach its lower surface transversely by a cut of the bistoury. The instrument then being immediately carried behind and beyond the limits of the disease, enables me to divide the tissues from above downwards with a second cut, which terminates the operation. It would be difficult to find a more simple mode or one that is more generally applicable.

C. *Appreciation*.—Transverse amputation of the tongue therefore should be reserved for those cases in which there is no opportunity for the formation of lateral flaps. The dividing the tumor by a crucial incision and then cauterizing its bottom, as *Delpech* did, (*Rev. Méd.*, 1832, t. II., p. 384,) is an objectionable process, which would be applicable only to cysts of a benign nature. The method of

Jaeger (*Journ. des Conn. Méd. Chir.*, t. I., p. 347), is too complicated, and requires too many instruments to find any advocates. The previous ligature upon the lingual artery, as practised by M. Flaubert, and which M. Mirault has made trial of, would not be useful except, if instead of the ligature en masse, we intended to make the excision at a very remote point upon the tongue. It is also with difficulty that I can comprehend why M. Regnoli, (*Gaz. Méd.*, 1838, p. 796,) in order to extirpate a tumor from the tongue should have found it necessary to incise the entire supra-hyoid region and to draw out the tongue through this opening, though the young girl, who was fourteen years of age, was cured.

D. When *hypertrophy* only exists, *compression*, as employed successfully by Freteau, (*Bull. de la Fac. de Méd.*, t. V., p. 264,) Delpech (*Revue Méd.*, 1835, t. I., pp. 330–337,) and many others, will almost always answer. M. Rey, (*Ibid.*, 1835, t. I., pp. 330–337,) who, in a case of this kind, states that he was obliged to have resort in one instance to the V excision, adds that the operation of Mirault, the father, was also performed for a hypertrophy, and not for a cancerous tumor. It is quite remarkable that M. Harris (*Bull. de Pér.*, t. XXVI., p. 93), and M. Mussey, (*Gaz. Méd.*, 1838, p. 394,) who believe themselves to have been the first who employed this process, should also have been under the necessity of making use of the V excision to cure a chronic tumefaction of the tongue. As to the rest, every tumor, whether scirrhus or carcinomatous, which does not penetrate too deeply and which projects at the periphery of the tongue, may be readily destroyed by the process of Faure or Louis, that is to say, by means of the scissors curved flatwise and the actual cautery. Those on the contrary, which, extending to the muscular tissue, are seen upon the surface or on one of the borders, without reaching too great a distance posteriorly, and which have not invaded either the entire breadth or thickness of the organ, require the employment of the bistoury by the process which I have pointed out, and which is somewhat analogous to the method of P. le Mnémonite. If the disease, though much extended on the surface, continues to be superficial, and that the tissues beneath it are sound, we must follow the indication given by Vallée and dissect and remove everything which is diseased, and respect and preserve everything which is not so. If it becomes necessary to destroy an entire half of the tongue, including therein its base, the ligature by the process of M. Mayor becomes applicable and even appears to me to be preferable to that of M. Mirault, while, should it become requisite to remove the whole tongue, the process of Home ought to have the preference, as well as in all those cases in which excision, after the manner of Boyer, is not sufficient for removing the tumor and central degenerescence. It is necessary to be remarked however, that in the process of M. J. Cloquet or M. Mirault, as well as in that of M. Maingault, there is no necessity of slitting up the whole length of the tongue before strangulating its base. I will add, in the patient of the surgeon of Angers, the ligature, by embedding itself into the tissues, became imprisoned there by allowing them to reunite over it in place of mortifying them; the tumor nevertheless was removed

and the tongue remained entire. As to the process of M. Regnoli, I do not know what to say of it.

E. *Subsequent Treatment*.—It is extremely rare, as has been shown by Tarbès, (*Clin des Hôp.*, t. II., p. 41,) that we are under the necessity, after these different kinds of operations, of having recourse to the various objects of dressing. If the contrary should be the case, the gusset (gousset) of Pibrac might become useful. Upon the supposition that there should occur an unpleasant hemorrhage, or one which the means above pointed out could not have effectually arrested, we should then have to have recourse to the ligature. In such cases we should be obliged to look for the lingual artery at its passage above the os hyoides, unless that the carotid itself would not also have to be included in the thread. It would, in fact, be advisable to commence there if the tongue was to be amputated near its root with the cutting instrument.

#### § IV.—*Palate*.

The mouth and the palate, as well as tongue and cheeks, sometimes contain *calculi*. Kruger (*Mém. de l'Acad. de Berlin*, t. VII., App., p. 130,) says he extracted a calculus from an abscess in the palate. A stone came out from the internal surface of the masseter in a patient mentioned by D. Pomarest, (Bonet, *Corps de Méd.*, t. IV., p. 102.) The vault of the palate is sometimes also the seat of *fibrous* or cancerous tumors. I have already given two examples of these in the chapter on tumors. M. Guyot (*Bull. de Fér.*, t. II., p. 262,) has successfully extirpated tumors of this kind, which did not differ from ordinary cancers. I have met many instances of those which, of the size of the thumb or a small egg, presented all the characters of fibrous tumors, and were solidly adherent to the bones. To remove them, all that is necessary would be, after having hooked them with an erigne, to dissect them with care, and afterwards to cauterize the wound with the red hot iron should any hemorrhage threaten.

### ARTICLE IX.—POSTERIOR FAUCES, (Isthme du Gouvier.)

#### § I.—*Hypertrophied Tonsils*.

The tonsils, after repeated inflammations, frequently remain so large as to interfere with deglutition, hearing and respiration. The induration they acquire at the same time, is the reason why for centuries past it has been believed that they had passed into the state of scirrhus. But since the time of Claudinus, and especially of B. Bell, the falsity of this opinion, which I am surprised to see revived in some modern works, has been generally acknowledged. All surgeons at the present time know that induration of the tonsils, with tumefaction, is nothing else but an hypertrophy, and that it never, or almost never, gives rise to scirrhus or cancer. The treatment which has been applied to it has greatly varied. Without mentioning scarifications, eulogized by Asclepiades, Celsus, Heister and Maurain, as well as by some of the moderns, and among others M. H. Berard,

(Fabre, *Thèse*, No. 133, Paris, 1832,) it has been attacked also by cauterization, the ligature, extirpation and excision.

A. *Cauterization*.—Mesué, who appears to have been the first who ventured to apply caustics to the tonsils, made use of the actual cautery. Brunus adopted the same practice, at least when it was his intention to destroy the whole disease. Mercatus, who followed, made use of a gold cautery moderately heated, and which he conducted through a canula. M. A. Severin, less exacting than Mercatus, contented himself with an iron instrument, and did not have recourse to it any more than his friend Affisius, except for tonsils with a large base. Wiseman, after having mentioned that Ed. Mol very successfully cauterized the tonsils by perforating them at several times with a red hot iron, nevertheless confesses that he prefers the employment of escharotics, which Junker, Heister and Freind also advise, under various forms. The lapis infernalis, successfully employed by Morand, is also sometimes in usage at the present day, but it possesses no advantage any more than sulphate of iron, copper or alumine, except in cases where the induration is recent and of but little extent. MM. Perronneaux, Roger, Sarmento, Quotard, and F. Hatin, who following MM. Bretonneau, Toirac, Guillon and myself, have proposed nitrate of silver against acute anginas, have also devised for this purpose caustic holders, which might possess some advantage, especially that of M. Sarmento. The red hot iron, which Louis seems to prefer, and which should be adopted if it was proposed to cauterize vigorously, is evidently applicable only to fungous tonsils, and in cases in which we were fearful of having left behind a portion of what we intended to have removed, and of seeing the disease repullulate and the blood escape in too large a quantity after the excision. But as these different circumstances, pointed out by Percy and Boyer, are but rare exceptions, it follows, even on receiving them as facts, that cauterization ought scarcely ever to be resorted to.

B. *The ligature*, devised for the purpose of avoiding hemorrhage with greater certainty, and giving less dread to the patient, and which has been a long time employed in France, had not, however, been distinctly recommended by any person before the time of Guillemeau, who, in order to apply it, made use of a sort of knot-tightening forceps arranged with considerable ingenuity. F. de Hilden is the second author who recommends it. The canula, provided with a canulated ring, and which he invented for this purpose, in order to conduct and tighten the thread, and which instrument has been revived as a new one by M. Smith, (*Journ. de Prog.*, etc., t. VI., p. 275,) has not been adopted any more than the instrument of Guillemeau. Cheselden, one of its principal partisans, applied it by means of a simple sound in cases where the tumor is as it were pediculated. In other cases, he passed a double thread through the gland by means of a curved needle, in order to strangulate the two halves separately. Sharp operated exclusively in this manner, which Lecat, following Castellanus, Levret and Heuermann, has modified in this point, particularly that from the color of his two strands of thread, being different, it is never possible to mistake them. Bell made use of a silver wire or catgut; inserted it in a slightly curved canula, which he introduced to the top of the pharynx through the corresponding nasal

fossa; extended its noose with the finger, placed it around the tonsil, and used his canula as a knot-tightener. Desault was satisfied with a Brittany thread conducted through the mouth upon a double erigne, and fastened by means of his ordinary knot-tightener. Before him Heuermann had maintained that the polypus instruments of Levret are those which are the best for this ligature, which, however, may be equally well applied by means of the chaplet instrument of M. Mayor, or after the manner of C. Siebold, by means of a silver wire introduced with the forceps. The inconveniences of the ligature, which had already been noticed by Van Swieten and Moscati, are so obvious to every person, and are so inherent in the operation itself, that no one now employs it, notwithstanding the successes attributed to it by Physick, so that it becomes difficult to understand the efforts made use of in England by MM. Chevallier and C. Bell to bring it again into repute.

C. *Extirpation*, which Celsus appears to have pointed out in these words: *oportet digito circumradere (tonsillas) et evellere*, was positively recommended by Paul of Egina, *ipsam totam (tonsillam) ex fundo per scapellum resecamus*, who performed it with a curved bistoury. Ali-Abbas had invented for this purpose a sort of hook which is called *senora*, and Abu'l Kasem a small knife in the form of a sickle. In the place of the *ankylotome* of Paul, J. Fabricius advises that we should first isolate the gland by means of an elevator, then seize it with the forceps and draw upon it adroitly in order that it may yield without difficulty, he says, and as it were of its own accord. It would be practicable, if it were necessary, to tear out the tonsils by enucleating them with the nail and finger, as was probably done in the time of Celsus; but this would be unnecessarily augmenting the sufferings of the patient, and any person may comprehend that such an eradication must necessarily be dangerous. Moreover, extirpation of the tonsils is entirely useless, and excision has long since been substituted for it. If, however, we should decide upon performing it, nothing would be more simple. An erigne, or the forceps of Museux, to draw and disengage the gland from between the pillars of the velum palati; and a narrow and blunt-pointed bistoury to divide it at its root, would answer, as in ordinary excision. Only we must take care not to go beyond the lateral limits of the pharynx, for then the venous plexus, or some vessels still more important, the carotid, for example, which is found on the sides of this muscular funnel, might become wounded, and give rise to a formidable hemorrhage.

D. *Excision*.—Though Aetius appears to have been the first who formally announced that we must only remove the prominent portion of the tonsils, and never extirpate them, excision nevertheless had been recommended before him. The operation which Asclepiades designates under the name of *homoiotome*, cannot be any other thing. Has not Celsus also described it in this phrase? *Si ne sic quidem resolvuntur, hamulo excipere et scapello excidere*. Those who since then have adopted it, have almost all of them endeavored to modify the process. Rhazes says that we should seize the tumor with an erigne, and retrench the fourth part of it; but according to him, it is an operation so dangerous that we ought rather to recur to broncho-

tomy. *Wiseman*, instead of using the hook and ankylotome of the ancients, or the curved bistoury and double erigne of *Mesuc*, commenced by ligating the tonsil, and afterwards made use of the thread as an erigne, while he was excising the gland with the scissors. *Moscatti*, who was at first a partisan of the ligature, which had already been proscribed by *Cavallini*, and who at a subsequent period practised excision with a curved bistoury, fixed upon a blade of wood, afterwards adopted another process: he commenced by making a crucial incision into the tonsil by means of a convex bistoury, after which he excised its four flaps separately, taking care to leave an interval of three or four days between each operation. *Maurain*, who properly censures the method of *Moscatti*, recommends with *Levret* that we should remove with a single cut the entire tumor, by means of curved scissors made expressly for the purpose. *Lecat* went back to the double erigne of *Heister*, and recommended a small concave knife with a blunt point, or curved and blunt scissors. At the same epoch *Foubert* recommended that we should embrace the gland with a polypus forceps, and make strong traction upon it in order to contuse the vessels while we were excising it with a single cut of the bistoury. *Caqué* greatly extols the simple erigne, then a blunt-pointed knife with a cutting edge which is almost straight, and bent into an angle upon its handle. *Louis* asserts that the ordinary bistoury will answer, and that if we divide the gland from below upwards, we shall be sure to prevent it from reversing itself upon the opening of the larynx, and exposing the patient to suffocation, as in the cases which gave so much alarm to *Wiseman* and *Moscatti*. *Museux* invented for this operation the forceps which bear his name, and maintained that when the tonsil is once seized hold of with this instrument, it is no longer possible for it to escape. *Desault* gave the preference to the ordinary double erigne, and the *kiotome*. *Desault's* instrument, though ingenious, is no longer employed. The blunt-pointed, straight bistoury is infinitely more convenient, and, as *Boyer* has remarked, in every respect deserves the preference. The reason why authors have varied so much in the manner of performing so simple an operation, is because, in intractable persons, children for example, and those whose mouth also is small and deep, or who open it with difficulty, it is sometimes attended with considerable embarrassment. A glance at the stages which compose the operation will enable me, I hope, to reduce to their just value the principal precepts of the surgeons who have just been cited.

I. *Speculum oris and depressors of the tongue*.—The first thing to be attended to is to keep the mouth of the patient open, and to control the movements of the tongue, from whence comes the different glossocatoches of the ancients, and the various kinds of *specula*, which followed from the time of *A. Paré* down to our epoch; from whence also comes the chevalet, the handle of which, curved in the shape of an S, enabled *Caqué* to draw the labial commissure backwards, and to keep the jaws separated; and the silver plate which was applied on the tongue, while its handle, a little more elevated, rests upon the lower dental arcade, which it permits us to depress; also that other instrument more complicated, proposed by *M. Lemaistre*, and afterwards by *M. Garnier*, and which, without interfering with the move-

ments of the operator, has the effect to keep the mouth firmly open and the tongue depressed; the plate of box-wood, or of ebony, bent at a right angle, and in other respects quite similar to the horn, which is used for raising up the heel of the shoe in putting it on, and which MM. Roche and Sanson consider very useful; from hence comes also the instrument of M. Colombat, the annular wedge of M. Saint-Yves, and the long handle with a disc of M. A. Bérard, &c. But a myrtle-leaf, or a spatula, the handle of a silver spoon, the finger, or a piece of cork, are full as good, and less embarrassing than those ingenious inventions, when we are actually under the necessity of attending to the mouth or tongue in this respect.

II. *To secure the tonsil.*—The *previous ligature* of Wiseman is evidently a method more fatiguing than excision itself. As to the *erigne*, it is to be apprehended, it is said, that if it is single it may lacerate the tissues and escape; that it is attended with too much difficulty to insert it on the contrary if it is double, or especially quadruple, as in the *forceps of Museux*. It is also objected to these last, that they interfere by their size with the movement of the other instruments, and that they are not easily supported by the patient. Finally, the *erigne* with three points, devised by *M. Marjolin*, would be still more embarrassing if it was necessary to disengage it before the end of the operation, than the instrument of the surgeon of Rheims. There can be no doubt that there is some truth in these objections, though most of the inconveniences pointed out are trifling. After all, the choice of the *erigne* is not here a matter of importance; provided that that which is single possesses a certain degree of solidity, that it has an arc of a certain extent, and seizes the gland behind, at the union of its outer third with its two inner thirds, it will enable us to make traction upon it with as much force, and with as little laceration of the tissues as a double *erigne*. *Louis* has had no reason to be dissatisfied with it, and I on my part have found it very useful in practice. The double *erigne* also, which was still used by *Desault* and *Boyer*, has no other inconvenience, in my opinion, than that of being a little more difficult to adjust. The *forceps of Museux*, though less easy of management, but preferred by *Dupuytren*, possess an advantage which is not found in the *erigne* of *M. Marjolin*; which is, of not incurring the risk when we withdraw them, of wounding the different parts of the mouth. The *erigne-forceps* of *M. Ricord* have no advantage over those of *M. Marjolin*. The same may be said of the *polypus forceps* of the shape of an *L* of *M. Chauvet*, those of *M. Saint-Yves*, and the *erigne* with four hooks of *M. Baudens*.

III. *The large blunt or probe-pointed bistouries*, and which are curved or straight, with a spring or fixed handle, being merely a reproduction of the ancient instruments, are entirely unnecessary, though they have been proposed by MM. *Blandin*, *Amussat*, *Ricord*, *Baudens*, and myself. As to the *cutting instrument*, the only choice at the present day is between the scissors and the probe-pointed bistoury. With the first we are more certain, especially in selecting the scissors with blunt or probe points curved on their flat side, particularly the *scissors of M. J. Cloquet*, (*Arch. Gén. de Méd.*, 2e sér., t. II., p. 124,) of removing nothing which we wish to pre-

serve. But the section which they make has less neatness, and they occupy somewhat more space in the pharynx and mouth than the bistoury. The gland, moreover, when pressed upon between their branches sometimes escapes from them, and compels us to make several cuts before we can divide it. In respect to the bistoury, if there is no longer any question except of those which are terminated by a blunt or rounded point, it is because that with the others we might easily wound the posterior wall of the pharynx, and with much facility also perforate its outer wall. Caqué's knife is too large, and the straight and narrowest bistoury is unquestionably the best that can be made use of. If the kiotome had not been recommended by a man so celebrated as Desault, and had been represented in a less favorable light by M. S. Cooper, it would scarcely have deserved to be mentioned.

IV. The instruments being once selected, it remains to know in what manner the excision should be performed. In making this excision from above downwards, as some have recommended, it is to be feared that the bistoury might end by wounding the base of the tongue, and that if the *gland* holds only by a pedicle, it may escape and be *reversed upon the larynx*; but it would then be so easy by passing the finger into the throat to bring it back into the mouth and to complete its extraction, that this difficulty, which had like to have happened to Wiseman and Moscati, is in fact rarely to be apprehended. Louis, who had a dread of it, says, that by cutting from below upwards, there would be no danger of such an accident, and that the tongue itself would thereby be protected from any injury. In acknowledging the justice of this principle, Boyer and Marjolin concluded nevertheless to adopt it only in part. According to them, if we run no risk of wounding the tongue, it is not the same with the *velum palati*, and to avoid also this last inconvenience they follow the recommendation of Richter, and first incise from above downwards, then from below upwards, terminating at the middle part of the tumor. I see nothing to censure in these precautions only that they are useless. M. Roux usually operates like Louis, and has no reason to be dissatisfied with his process. Up to the present time I have had no reason to find fault with it; provided we take care to make the tonsil sufficiently prominent by drawing it towards us, and by slightly pressing it with the flat of the instrument against the arches of the palate, as if for the purpose of grazing its curve, we obtain one of the neatest and most rapid sections possible, without having in reality any thing to apprehend.

*a. Ordinary Process.*—The patient being placed upon a chair in front of a window properly lighted, is to have the head steadied and more or less turned back by an assistant. The surgeon placed in front, after having properly shaped a piece of cork, inserts it as far in as possible, and adjusts it vertically between the molar teeth on one side, in order to keep the jaws apart. Having caused the tongue to be depressed should it be in the way, and the commissure of the lips to be drawn backwards and outwards, the tonsil is to be secured and firmly embraced by the erigne at its postero-inferior portion, with the left hand for the left side, and with the right hand for the right side. After having drawn it out and disengaged it from

between the arches, he takes in his other hand the bistoury, which has been wrapped in a linen band up to within ten or fifteen lines from its point; then passes it between the erigne and the tongue, under the base of the gland; turns its cutting edge upwards, and cuts on its whole length by saw-like movements, as if in order to make it describe the arc of a circle, which is to finish at the base of the uvula, and in this manner separates with a single cut the entire hypertrophied portion of the tumor. Withdrawing at the same time the bistoury, the erigne and the excised mass, he immediately removes from between the jaws the cork which is fatiguing them, then makes the patient spit out and gives him cold water, or vinegar and water, to rinse out his mouth and to gargle. If one of the tonsils only was affected the operation is finished. When both are diseased we wait a few minutes; the blood ceases to flow, and we proceed after the same precepts to the excision of the other. We may in fact not remove them until after an interval of some days, should the patient be too much fatigued or absolutely desire it; but in general they prefer to be operated on at the same sitting rather than have it repeated after an interval of time, and the pain that they experience is in general so trivial that they can support it without any very great dread.

*b. Process of the Author.*—In tractable or reasonable persons, the process that I follow by preference, differs from the preceding in these particulars:—1. I place nothing around the bistoury or between the teeth. 2. I require no person to depress the tongue. 3. I make use of the simple erigne, possessing some degree of strength, and properly curved into an arc or hook. I hold the mouth of the patient open, and depress his tongue with the forefinger if I find it necessary. I then immediately plunge the point of the erigne into the body of the tonsil, from behind forwards, and from within outwards. The tractions I afterwards make upon the tumor to bring it towards the side of the mouth and uvula, force the patient to open his jaws, by paralyzing the contractions of the tongue. Making use of it as a guide to the bistoury, which I glide in flatwise, the back part first between it and the dorsum of the tongue, the erigne enables me to direct the instrument with certainty, and without having any need of seeing it as far back as to the bottom of the pharynx, to elevate its cutting edge when it is properly adjusted, and to terminate the operation while the wrist is inclined outwards, in as little time and with as little embarrassment to the patient as possible. It is entirely useless to wrap up the heel of the bistoury; but if we should take this precaution, it would be better to make use of a strip of adhesive plaster than a linen band.

*c. Another process of the Author.*—The operation I have just described is so simple and easy, that I can scarcely see any reason for simplifying it more. To effect this object however, new instruments have been devised, which may possess some advantages. In order to improve the kiotome of Desault, Physick, M. Warren, M. Fahnestock, in America, and M. Toirac in France, have each one for the purpose of dividing the tonsil, proposed a sort of guillotine, which is constructed with a ring to embrace the gland, and with a movable blade in the form of a large arrow, in those of MM. Warren and

Toirac, and in form of a circle in that of M. Falnestock. The one which I make use of, after having modified it, bears a ring near its handle, and also a shifting and sliding point, (*pique à bascule et à coulisse*;) in order to raise up and fix the body which is to be excised. This instrument being introduced open in the manner of a spoon to the bottom of the mouth, serves very well to embrace the tonsil, the summit of which is immediately transfixed by the point, which must be made to slide an inch backwards; by pressing on the ring of this point, we draw into the ring as much as we wish of the tonsil. We then draw rapidly the cutting circle of the tonsillitome with one hand, while we steady its shaft with the other, which terminates the operation. This is an instrument which should be preserved for children, intractable persons, and those who open their mouth with difficulty, and also for surgeons who are not accustomed to operations.

V. *Subsequent Treatment*.—If the bleeding should not immediately cease, a solution of alum, eau de Rabel, or any other styptic liquor should be immediately given as a gargle, or should be applied naked to the wound by means of a forceps, if it were necessary to make it very active or concentrated. In cases of imminent danger, the actual cautery constitutes a last resource, which must not be neglected, and which is much more efficacious than the very complicated mode of compression proposed by Jourdain, or the agaric holder of M. Hervez de Chegoin. In an adult whom I operated upon in the beginning of 1831, at the house of Mad. Reboul, the loss of blood was so considerable at the expiration of two hours, that it became necessary to apply powdered alum immediately upon the wound. I have seen the same thing since in one of my patients, and in another who had been operated upon in the medical wards at the Hospital of La Charité. If some inexpert person should have opened the carotid, as Ténon or Portal, and A. Burns, Béclard and Barclay state that they have seen, the ligature upon the primitive trunk alone would still offer some chance of recovery. A frightful hemorrhage followed some scarifications which had been made upon the tonsils, and the woman was dead when M. Champion came to visit her. In respect to the remainder of the treatment, it consists of emollient gargles and diluent drinks; and the diet of broths and light soups, and afterwards food that is somewhat more generous. In general, scarcely any fever supervenes, and at the fourth or fifth day the health is in a great measure re-established.

## § II.—*Abscesses and Incision of the Tonsil.*

The surgeon is sometimes called upon to lay open with the instrument abscesses which form in the substance of the tonsils, as the result of phlegmonous inflammation. The sharp-pointed knife of Hippocrates and Celsus, the long bistoury and needle used by Leonidas, the razor of Lanfranc, the small piece of polished wood of Platner, the sagitella of Arcularius, the bird-beaked bistoury devised by Vigo, the pharyngotome of J. L. Petit, that of Jourdain, and the lancet of Roger of Parma, are, when it becomes advisable to perform this small operation, all advantageously replaced by the ordinary bistoury, when it is required to perform this small operation. Pressure with

the finger, a stroke with the nail, or an emetic properly administered, also very frequently answer. We also hold the mouth and patient in the same manner as for the excision of the tonsils, and the bistoury is to be wrapped in a strip of plaster to six lines from its point before we should undertake to plunge it into the abscess. The laying open of collections which are sometimes formed in the substance of the velum palati, in the uvula and walls of the pharynx, or even at the base of the tongue, is performed with the same precautions, and requires no other attentions.

### § III.—*Cancer of the Tonsils.*

Because cancer of the tonsils is rare, we must not therefore conclude that it is never met with. I have already encountered five cases, all belonging to the class of encephaloid cancers. Their situation and their relations with the large vessels of the neck have hitherto intimidated surgeons and prevented them from meddling with them. I have however in one instance extirpated a cancer of the tonsil in 1836, at the hospital of La Charité, and I did not find the operation very difficult. The patient, who was a countryman of 68 years of age, had suffered from his left tonsil for the space of two years; the tumor, which was bleeding, and already ulcerated and in a putrilaginous (putrilagineuse) state, almost completely filled up the pharynx, occupied a part of the nasal fossæ, and crowded forward the velum palati; suffocation was imminent. Having laid bare the primitive carotid, and passed a thread under it, as a precautionary ligature, I secured the tumor very far back by means of a double erigne, and drew it strongly forwards towards the median line. A small knife curved flatwise and with a fixed handle, then enabled me to lay open the left side of the velum and to extirpate the entire tumor from below upwards, and from within outwards. Perceiving the hemorrhage was trifling, I proceeded without stopping, and by another external wound, to the removal of a degenerate lymphatic ganglion, which lay against the pharynx in the lower part of the parotid region. The precautionary ligature became useless, and I removed it on the following day; at first nothing unpleasant occurred, and the wound had become cleansed, when a diarrhea with adynamia, and symptoms of purulent infection, developed themselves on the 10th day, ending in death on the 17th. An examination of the parts showed that there was nothing of a cancerous nature either on the inner or outer side of the pharynx, and that all the large vessels had been respected. The wounds were in great part cicatrized, and we found no appreciable lesion in the viscera; the large intestine alone appearing to be inflamed. This unfortunate termination, nevertheless, proves that the operation is possible, and that there may be sometimes occasion for undertaking removal of cancers of the throat like those of other organs.

### § IV.—*Excision of the Uvula.*

The elongation of the uvula, either by infiltration, inflammation or degenerescence, was an affection which the ancients paid much more attention to than the moderns, and which perhaps, merits more

attention than is generally accorded to it at the present day. In consequence of its contact with the base of the tongue, the apex of the uvula produces a most unpleasant titillation (agacement) in the throat, causes sometimes symptoms which appear to be connected with affections of a much more serious character, as for example, gastritis and phthisis, and which might lead to the commission of dangerous errors in the diagnosis, as well as in the treatment, if the surgeon should be ignorant of these circumstances. Consequently it is important that we should not wait too long before applying a remedy for the alterations of the uvula, and that we should not forget that its ablation is frequently, as Physick and Beckern moreover have shown, the only means of curing certain obstinate symptoms, which might lead to the supposition that there existed a serious malady.

A. *Cauterization*.—Its inflammation even when acute, should it have yet made but little progress, very readily yields to cauterization with nitrate of silver. I have used it like M. Toriac in many cases, and have had every reason to be satisfied with it. The melange eulogized by Demosthenes, and the caustics proposed by Galen, are at most applicable to cases of serous infiltration. The gold or iron cauteries made use of by Montagnana and Arculanus, the nitric and sulphuric acids employed by Vigier and Nuck, are very properly abandoned. Nobody at the present day would venture to imitate the absurd advice given by Mesué, and afterwards revived by Nuck and Bass, that is to say, to make traction upon the hair of the head to such degree as to tear the skin from the cranium, after having tied them with a ribbon near their roots, and united them together into a topknot.

B. *Astringents*.—Sal-ammoniac and the gall-nut according to S. Largus, the green shell of walnuts according to Galen, burnt alum mentioned by Rhazes, and pepper or ginger still recommended by Purmann, are scarcely in use at the present time, except by old women and country people, who, when the uvula is *down*, believe also that they can raise it up by placing under it a silver tea-spoon heated to a very considerable degree.

C. The *ligature* applied to the base of the uvula by means of the canulated ring of Castellanus, as Paré recommends, or by the ligature-holder of F. de Hilden and Scultetus, or in any other manner, though not as dangerous as Dionis considers, is nevertheless useless, and excision with a cutting instrument is the only means, which at the present day is resorted to for the chronic lesions, which have caused the elongation, or what is called the falling down of the uvula.

D. *Excision*.—It is moreover an operation which has been performed at every epoch, and in quite a great variety of modes. Hippocrates treats of it and recommends that it should be done with address; Celsus and Galen followed the same process. Paul had instruments expressly made for it; a *staphylagrum* to hold the organ, a *staphylotome* to divide it, and a *staphylocaustum* to cauterize the wound. He also speaks of another instrument invented by Serapion. Mesué, who proscribes the entire removal of the uvula, excised it with a gold bistoury heated at the fire, after having secured it in the ring of a sheath made expressly for this purpose.

In place of this sheath, G. de Salicet recommends that we should make use of a tube of elder, in which he placed the uvula in order to divide it, either by means of the hot iron or with the common bistoury. Guy de Chauliac recommends a forceps or an erigne, a concave bistoury or scissors. The scissors, without forceps or erigne, answered with J. Fabricius, who afterwards cauterized the wound in order to re-excite its vitality. A Norwegian peasant named Thorbern, devised an instrument somewhat similar to that of Mesué and Arnaud, that is to say, a species of kiotome, which is opened in order that the uvula may become secured in a circular perforation placed near its extremity, and which it is only necessary to allow to shut up of itself for the excision to be instantly effected. Job-a-Meckren, who has seen the uvula extend as far as the lips, considers that we can use nothing more convenient than the scissors with long blades. Thorbern's instrument, improved by Raw, and soon after revived by Bass, under the form of a spatula provided with a cutting tongue, did not prevent Fritze from attempting still another modification to it since. Levret, who was also an advocate of the ligature, has eulogized scissors with a concave cutting edge, the same as for the tonsils and also polypus forceps. Richter found that scissors with a blunt point answered the purpose very well, and B. Bell had adopted a curved blunt-pointed bistoury nearly similar to that of Pott for hernia. The scissors of Percy, however, for the excision of the uvula are those which have been constructed with the most ingenuity and simplicity; a prolongation of three to four lines bent into a right angle terminates one of their blades, and prevents the uvula from making its escape from them, as soon as it has been secured. The only objection to them, as well as to most of the inventions mentioned above, is that they are not indispensable, and can be made use of only for this purpose; from whence it follows, that the new staphylotomes proposed by MM. Rousseau and Bennatti are also useless instruments. A slender ring-forceps with very long handles, and with its beak armed with three mice-teeth, is preferable to all the others.

*E. Operative Process.*—The patient is placed in the same manner as for excision of the tonsils. The surgeon having in his left hand a fine erigne, or a dressing, or polypus, or the claw forceps which I have described, secures the uvula, inclines it forwards and a little to the right, and then with a straight and blunt-pointed scissors divides it with a single cut at some distance from its base.

F. It is not under the idle pretext of preventing it from falling into the larynx that we endeavor, in the first place, to secure the uvula, but because from its being supple and very movable it might, without that precaution, escape from the blades of the instrument. Oribases, Rhazes, Avenzoar, &c., were wrong in saying that its entire ablation is dangerous, and that it always alters the respiration and voice. S. Braun is still further from the truth in asserting that it constantly produces loss of speech. The case cited by Wedel, and which tends to prove that the aliments and the drinks then ascend through the nose, is evidently only an exception. The observations of Scheffler, Becken, Myrrhen, and Physick, and those of my own, satisfactorily prove that the loss of an organ like this rarely

produces any disturbance in the organism. It is better even to take away too much than too little, in order that we may not be obliged to repeat the operation; moreover the disengorgement which soon takes place, causes the uvula, whose base was more or less concealed in the velum of the palate, ultimately to become much longer than would have been at first supposed.

#### § V.—*Staphyloraphy.*

Abnormal divisions of the velum palati are, as in the lips, sometimes congenital and sometimes acquired. If the first are almost always situated upon the median line, it is generally because the cavity of the vault of the palate has not filled up posteriorly, and that its two halves are not united at that part at the usual period. They are, however, sometimes found a little to one side, but they have never yet been seen double. The second, (or acquired,) which are ordinarily the result of traumatic lesions, and more especially of syphilitic ulcerations, are encountered to the right and to the left as well as in the middle, and under the form of notches, the depth of which is usually limited by the border of the vault of the palate, while the congenital extend often to the dental arcade, and to such degree as to be continuous with the simple or double harelip should the patient be simultaneously affected with that.

A. *History.*—Nothing in the ancients indicates that they ever undertook to cure this malorganization. Roland, Harnemann, and Ténon, who have mentioned and seen it, do not speak of its treatment. The moderns, more enterprising or more skilful, have endeavored to fill up this void, and their efforts have been crowned with the most fortunate results. In casting the eye upon a fissure of the uvula, the idea of staphyloraphy must have frequently presented itself to the mind. The trials which M. Colombe states that he made of it in the year 1813 on the dead body, and which he wished to repeat in 1815 on a patient who refused to submit to it, have not been known to the public. That of which M. Graefe published the details in the *Journal of Hufeland* for 1817, and which he dates at the end of 1816, not having succeeded, has also passed unnoticed. It is therefore to M. Roux for whom it was reserved to call attention to this subject. In 1819 a young physician, M. Stephenson, presented to him the first opportunity for this operation. It succeeded to his wishes, and M. Stephenson himself made known his cure in a thesis, supported at London in 1821. In 1822, the following year, M. Alcock was no less fortunate than the surgeon of Paris. It was then that the rights of M. Graefe to priority were appealed to by his countrymen. There is every reason, however, to believe that staphyloraphy had been practised in former times. Robert, in fact, says in his memoirs on various medical subjects, published in 1761: "A child had the palate *cleft* from the velum to the incisor teeth. M. Lemonnier, a very skilful dentist, endeavored and succeeded in *reuniting the two borders of the cleft*, first inserted *several points of suture* in order to keep them approximated, and afterwards *abraded* them with a cutting instrument. An inflammation supervened, which terminated in suppuration, and was followed by the reunion of the two lips of the artificial wound. The child was perfectly cured."

The words: child, a cleft, suture, the abrasion, the approximation, and the cure,—all this, notwithstanding the somewhat obscure language of Robert, scarcely permits us to doubt that his dentist must have in reality had recourse to staphyloraphy, and not to the suture of a simple perforation of the vault of the palate. This operation therefore is, in every point of view, a discovery entirely French. It is one, moreover, which is so frequently required, that up to the present time, 1839, M. Roux has himself performed it nearly one hundred times. M. Jousselin of Liege has obtained two cures and M. Baubien a third. M. Caillot of Strasbourg has published a fourth, and in 1828 M. J. Cloquet a fifth. M. Morisseau has published a sixth, obtained by him at Sablé, in a young girl aged twenty years. Bonfils communicated another about the same time to the Society of Practical Medicine at Paris. MM. Smith, Hosack, Stevens and Warren, in America, M. Dieffenbach and others in Germany, and MM. Philippart, A. Bérard, (*Arch. Gén. de Méd.*, 2e sér., t. IV., p. 629,) A. Thierry and Baraduc, (private communication,) in France, have had every reason to be satisfied with it. I have myself been no less fortunate in one instance. M. Roux performs it at the present time in the same manner that he did in 1819. In Germany, in place of the word *uranoraphy*, which M. Graefe proposed, others have wished to substitute the terms *velosynthesis*, *kyonoraphy*, *uraniskoraphy*, &c. MM. Doniges, Ebel, Hruby, Dieffenbach, Wernecke, Lesenberg, Schwerdt and Krimer, have all endeavored to simplify the instrumental part of it; and in England M. Alcock himself no longer follows the method of M. Roux in all its particulars. All the stages of the operation have been discussed, and deserve to be so.

I. *Abrasion of the Cleft*.—*Cauterization* by means of muriatic and sulphuric acid, or caustic potash, as attempted by M. Graefe, or with the tincture cantharides, lapis infernalis, and even the hot iron, as proposed by MM. Ebel, Wernecke and Doniges, answer a no better purpose for *abrading* the fissure of the velum palati than that of the lips. *Excision* is indispensable in both cases. M. Roux, by means of the *dressing forceps*, somewhat concave and slender, successively seizes the two halves of the uvula or of its division near their free extremity, taking care to include only a very small portion of their border; then detaches from them, by proceeding from below upwards or from behind forwards, a strip of tissue a line thick, which he prolongs as far as their angle of reunion, and even a little beyond, if the bony vault remain intact. For that purpose a *straight blunt-pointed and very narrow bistoury*, moved in the manner of a small saw, appears to him preferable to the scissors, which are bent into an angle upon their handle near their heel, and which he at first proposed, and which he even still sometimes uses to commence this excision. In the beginning M. Graefe, in order to carry out the indication in question, made use of, first, a *long forceps*, curved back laterally near their points and terminating in a double erigne; second, of an *uranotome*, which is too complicated for me to attempt to describe here. Dr. Hruby has found that curved scissors, like those of *Muscux*, terminated in the form of crutches, firmly secure the velum during the time of the excision. The forceps of M. Graefe, with or without hooks, have appeared sufficient to M. Dief-

fenbach, who, for the abrasion properly so called, has contrived a small knife, a good idea of which would be conveyed by a lancet which was narrow at its heel and mounted upon a long handle. Finally, M. Schwerdt differs only from the preceding authors in not having his forceps bifurcated at their extremity.

II. *Approximation*.—The interrupted *suture*, the only one which in these cases can enable us to keep the two abraded edges in contact, are nevertheless applied in different ways.

a. *The needles* of M. Roux, which are short, flat and curved, in the manner of a hook, are nevertheless broad at their heel, upon which as in all other needles is placed a large square eye. The *ligature* which he threads them with is composed of four or five strands, properly waxed and about two feet long. His *needle-holder*, already known in the arts, is a sort of forceps having a groove on the inner side of its branches, and which are tightened or relaxed at pleasure by means of a ring.

b. Those which M. Graefe made trial of in 1816, represent very nearly the half of an ellipse. They are of less breadth but greater length than those of M. Roux, but their eye is much more elongated and perforates them at the side, as in the ancient suture needles. The forceps designed for inserting them is not traversed by any stem. Two rings, which are two inches apart, and which support two lateral uprights, open or shut it by gliding towards its extremity or its handle. At the present time the needles of M. Graefe are almost straight and terminated in a spear point. He has, moreover, bent his former needle-holder into an angle near its point, in order that when the needles are fixed by their border into the root which the branches of this instrument present, they may transform it into a legitimate hook. Finally, M. Graefe has dispensed with the rings of this needle-holder, which at the present day consists only of a jointed forceps, the movable branch of which is vibrating as in the concealed lithotome.

c. The needles of Ebel, which are straight, sharp pointed, and broader in the middle than at the heel, have, like those of M. Roux, a square opening to receive the thread. Those of M. Alcock are curved into an elongated circle, and are almost round. M. Dieffenbach has devised some which resemble a small punch. They have no eye, are straight or slightly concave, hollow in their posterior half, and may receive a leaden wire, which their inventor prefers to any other substance, and which they readily draw after them. His needle-holder, still more simple than that of M. Graefe, is in fact nothing more than a ring forceps, whose branches, which are a fourth part only of the length of the handles, are bent almost into a right angle in front near their point.

d. The needle and needle-holder of M. Doniges, make but one instrument. It consists of a long stem supported upon a handle of ebony, slightly bent posteriorly, and terminated in front by a needle hook pierced near its point and hollowed on its convexity to receive the thread. That of M. Lesenberg differs from it only in this, that it is formed of two parallel branches, which are separated or approximated by the same mechanism as the first needle-holder of M. Graefe; in such manner that all that is required is to open it after it has perforated the parts, in order that the thread that it has conducted may

be free, and that we may withdraw the needle without acting upon the ligature. M. Schwerdt, in adopting this needle, has proposed that we should attach to it the bascule branch of the last needle-holder of M. Graefe, in order to curtail it of the shifting rings of M. Doniges.

*e. M. de Villemur* has contrived some which are altogether different. His, while being retained in the needle-holder, are straight. Issuing from their sheath, from which a central stem enables us to expel them, they assume the curvature of the needles of M. Roux. As we push them from before backwards, they fall naturally into the pharynx, from whence they are to be withdrawn gradually by means of a dressing forceps. The two ends of each thread being brought forward and knotted out of the mouth, transform the ligature into a great circle, the noose of which it suffices to draw by its side, to make its broad portion slide backwards into the pharynx, after which we untie the knot and terminate as in the other methods.

III. *To knot the threads.*—The ligatures being once adjusted, every thing is not yet finished; they are also to be knotted and fastened. In France it would be difficult to comprehend why for this part of the operation it would be necessary, as M. Graefe recommends, to add other instruments to those already mentioned: 1st, a small hollow cylinder, pierced upon its sides; 2nd, a forceps bent into an angle on its back near its handle, and hollowed out with two grooves on the outer surface and each side of its point; 3d, a screw, or species of stopper, modelled after the preceding ring; 4th, a second forceps, straight, and with a handle like the ordinary caustic-holder for the lapis infernalis; and 5th, a long steel stem, mounted upon a handle, dilated and cut into a square shape at its free extremity, where are situated two openings to receive the two halves of the ligature and to form in itself a legitimate knot-tightener. This display of useless objects is sufficient of itself to make known their inconveniences, without the necessity of my particularizing them. M. Doniges in proposing the surgeon's knot as a substitute for the instruments of M. Graefe, a sort of crutch, cleft at the two ends of its transverse piece to receive the two ends of the thread which are to be drawn with one hand, while with the other we push this instrument towards the suture, has doubtless forgotten that the fingers would attain this object infinitely better. Nor can I see what advantage in reality M. Krimer can find in the employment of gold screws, rather than those of iron, like those of M. Graefe, of black threads rather than white, and those that are oiled in preference to those that are waxed. The method of M. Roux is still more simple and more natural. This surgeon, after having seized and passed the two ends of each ligature one into the other, makes a simple knot, which the forefingers directed to the bottom of the mouth, enable him to tighten as powerfully as he wishes. An assistant immediately embraces this knot with a ring forceps, and holds it firmly, in order that it may not be relaxed, while the operator is occupied with fastening it definitively by means of a second knot formed in the same manner, and outside of which we are afterwards to divide by a cut of the scissors, each of the superfluous portions of the threads of the ligature.

*B. Operative Process.*—Staphyloraphy, properly speaking, is not either a difficult or a painful operation; but being long, delicate, and fatiguing,

it requires much endurance on the part of the patient, and even on that of the operator. Consequently it cannot be performed except upon those who desire it, who are fully sensible of its importance, and who have made up their minds to submit to it. It rarely happens, therefore, that it is attempted in children under the age of from 12 to 15 years. It exacts no precautions of regimen; only that the individuals should in other respects be healthy. Diseases of the gastropulmonary passages would especially compromise its success, from the cough, sneezing, and necessity of spitting, which so frequently accompany them.

I. The different instruments, and which are to be prepared beforehand, are composed of: 1st, six flattened regular and pliant ligatures; 2nd, twelve needles, one threaded at each end of the ligatures; 3d, an ordinary needle-holder, or that of M. Dieffenbach, if the needles of M. Ebel, which are almost straight, should be preferred; 4th, a good pair of dressing forceps, the branches of which being a little concave, should not touch each other exactly when they are shut, except at their point, or better still, the claw forceps; 5th, a straight, blunt-pointed bistoury, narrower than that which is generally carried in the surgeon's case, or a very sharp-pointed and very narrow straight bistoury; 6th, excision scissors, and straight scissors, for dividing the ligatures; 7th, corks hollowed out into a gutter at each extremity, to accommodate themselves to the form of the dental arcades; 8th, a spoon intended for depressing the tongue in case of necessity; 9th, a number of towels, an aleze, cold water, a glass, basin, and also a small quantity of vinegar.

II. *Situation.*—The patient, provided with an aleze, and wrapped in a napkin and seated with his head supported by an assistant, should be placed in a powerful light, as for the excision of the tonsils. A second assistant stands ready to hand, as may be required, the basin and the water as well as the instruments.

*a. First stage.*—The operator being placed in front and on a chair, properly elevated, first introduces the corks between the molar arcades on either side; then seizes the right border of the division, by means of a forceps, in his left hand; directs the needle-holder, which has been threaded, into the pharynx with his right hand; brings it forwards and endeavors to make its point fall at three or four lines outside of and near the lower part of the fissure, in order that it may perforate the velum. Seizing hold of this needle by its point with the forceps transversely, after it has penetrated as far as possible into the mouth, he detaches its heel at the moment when the assistant opens the needle-holder, and without exercising the least movement upon it; he then removes this last instrument, takes the forceps in his right hand, draws the needle entirely towards him and brings it out of the mouth, while it fetches the ligature after it. The patient being fatigued, is under the necessity of spitting and of reposing for an instant. The jaws are then freed of the corks by which they were held apart, before proceeding to do on the left side with the second needle and the other end of the thread, by changing hands, what has already been done on the right. In order that they may not be confounded with those which are to follow, it is advisable to knot the free extremities of this first ligature and to depress its noose a little

into the bottom of the throat, in order that it may not interfere with the application of the others. The two extremities of it are drawn towards the commissures, and brought up by the assistant on the sides of the head. The surgeon then places the second and afterwards the third ligature, if he deems it necessary, with the same precautions and in the same manner, leaving between them nearly the same interval.

*b. Second stage.*—After having depressed, to one or two inches, the noose of each thread while pushing them backward, in order not to run the risk of dividing them with the bistoury or angular scissors (*ciseaux coudés*), the operator embraces the left lip of the cleft at the end of the uvula; commences with the scissors the excision of the thin strip which he intends to remove, and which the forceps is not to let go of, while he continues to separate it with the bistoury as high up as the bony vault; performs the same manœuvre on the right lip with the left hand, and returns to the use of the scissors, in order to regularize this abrasion, if the bistoury has not been made to act in a uniform manner on all the points of the abnormal division. The blood flows out, obstructs the pharynx and very frequently collects in clots about the threads. The patient requires to be relieved from it, and to gargle and to remain tranquil for some moments. In other respects the most difficult part of the operation is now completed.

*c. Third stage.*—*The ligatures are to be now identified* and to be arranged in order, that they may be readily found again, and then successively knotted, commencing with that below. When the separation is considerable, and its coaptation appears to be attended with difficulty, M. Roux detaches each of its lips from the posterior border of the palatine bone by a transverse incision of from four to six lines in depth. The two halves of the velum being then no longer restrained by the hard parts, yield and approach each other with an astonishing facility. It is the mode of preventing all dangerous traction on the part of the threads, and the new wound which has been made, afterwards spontaneously closes without necessarily giving us any uneasiness. In order to remedy the same inconvenience, M. Dieffenbach finds that a longitudinal incision at four lines external to and on each side of the abnormal fissure, is infinitely preferable to that of M. Roux, as it possesses all its advantages without having any of its inconveniences; that it also heals up of itself, and without interfering with the relations of the palatine vault, admits of a very decided elongation throughout their whole extent, of the flaps that we wish to bring together. These two modifications are not unimportant, and should be adopted; the first when a separation of the bones is complicated with a fissure of the soft parts; the second, which is more common, when we have only to overcome the resistance of these last, and the retraction of the muscles of the palate.

*C. Subsequent Treatment.*—After the ligatures are once knotted the operation is finished; no dressing is required; the patient is to remain quiet, without speaking, and be careful not to laugh, cough, vomit, spit or sneeze, and to take only broths or light soups, until the suture has acquired some degree of solidity. On the fourth day the first thread, that is, the middle one, may be removed; the second or

highest on the day after, and the third not until the sixth day. It is to be understood that they are to be left one or two days longer should the agglutination not appear to have been completed at the ordinary period. It need not be remarked also that, in order to relieve the tissues of them, we are to confine ourselves to dividing them upon the side of the knot, which is to be held and then withdrawn with the forceps. Nevertheless the operation quite frequently fails. A young girl, whom I saw at the Hotel Dieu, was operated upon for it five times without success. Many patients of M. Roux have succumbed in consequence of it, and I have seen a certain number that this surgeon had operated upon without any benefit. Other practitioners have procured a still smaller amount of successful results than M. Roux, so that it is not prudent to undertake it except under favorable circumstances, and in patients, for example, who are in good health, tractable and between fifteen and fifty years of age.

D. *Modifications.*—If reunion has been accomplished only towards the uvula, as frequently happens when the fissure is prolonged upon the median line of the jaw, it should not be the source of any anxiety. Quite frequently the opening which results from it disappears without any other treatment, after the expiration of a greater or less length of time, which result moreover is to be promoted by inflaming the edges with the lapis infernalis, as I have done and seen M. Roux do, or with the nitrate of mercury, as has been successfully done by M. J. Cloquet. After all, the patient would be rid of his trouble with an aperture only, if there were not other resources, and if *palato-plasty* was not at our command for an accident of this kind.

I. *Cauterization.*—There is another method yet, which is repeated cauterization at the superior angle of the fissure, either by a small bird-beaked cautery, or the nitrate of silver, as proposed by M. Henry de Lisieux, which method has been successfully employed by M. J. Cloquet, in order to entirely dispense with, or as a substitute for, staphyloraphy.

II. *Modifications.*—*Process of the Author.*—In place of beginning by adjusting the threads, I commence with rawing the borders of the fissure; for that purpose I seize its left free border either with the claw forceps or that which I have pointed out as the one to be preferred, in speaking of the excision of the uvula, in order to cut off a strip from it and afterwards to operate in the same manner on the other side. As the small knife of M. Dieffenbach might, if necessary, be replaced by a keratome or by a lancet of some length, secured by being wrapped in a strip of plaster, or even by a common straight bistoury, and which has no other inconvenience than that of incurring the risk of wounding the posterior wall of the pharynx, I should not hesitate to make use of it in place of the blunt-pointed bistoury; but a straight, very sharp, and very narrow bistoury is much better still. Being plunged through the velum palati from the mouth towards the pharynx, and very near the fissure which is to be excised, and afterwards conducted parallel to this fissure, at first in front or towards the bones or from below upwards, then towards the uvula, a strip is readily separated from it, the extremities of which, being the last that

are detached, evidently render the excision of the whole more certain and more easy by furnishing a double support to the instrument up to the end of the operation. I now wait a few minutes, and, as soon as the blood no longer flows, I adjust the ligatures with the flexible needles and needle-holder of M. Villemur,—that is to say, from the mouth towards the pharynx, or from before backwards, as is preferred by M. Bérard, (*Arch. Gén. de Méd.*, 2e série, t. IV., p. 629.) The rest of the operation requires no particular directions: I succeeded in this manner, in 1837, in a young man at the hospital of La Charité. M. A. Berard was no less fortunate in another case. But in a young girl whom I operated upon in the same manner in February, 1839, the reunion did not continue.

III. An instrument furnished with straight needles, carried from before backwards, and which secures the velum by embracing it, and brings back the needles and the thread at the same time through the fissure, would simplify every step of the operation, and has lately been made, at my request, by MM. Chopinière and Foratier, pupils of the hospitals. M. Beaumont, (*Med.-Chir. Review*, Oct., 1838, p. 148; *Enc. des Sc. Méd.*, 1838, p. 119,) with the view of more readily applying the suture to vesico-vaginal and recto-vaginal fistulas, also makes use of a sort of needle-forceps, which enables him to introduce and draw the thread through the staphyloraphy in one movement.

IV. In a boy eleven years of age, in whom a fissure was made in the palate by a piece of wood, *M. Friso* succeeded completely by making use of a blunt-pointed bistoury to excise the parts, and of a long dissecting forceps, provided with a sheath, for a needle-holder. A small hook, mounted upon a leaden handle, answered the purpose with M. Philipart; and M. Smith, rejecting the complicated apparatus of M. Hosack, finds nothing more required to introduce all his threads than a hook-shaped lance, (*lance à crochet*.)

V. M. Montain's clasp is too fatiguing to be generally adopted. Finally, if the fissure should continue near the incisor teeth we might, as M. Sanson (*Diday, Thèse de Concours*, 1839, p. 25) did in one instance with success, shut it up by means of a flap borrowed from the upper lip.

[*Staphyloraphy*.—From a recent elaborate work of the celebrated Dieffenbach, (*Die Operative Chirurgie*, Leipzig, 1845—see also condensed abregé of this work in the *Dublin Journal of Medical Science*, Nov., 1845, No. LXXXIII., vol. XXVIII., p. 227—249,) it would appear that this surgeon now dispenses with the usual preparative process of familiarizing the parts to the touch of the instruments, fingers, &c., before proceeding to the operation, from having himself found it impracticable, and also from patients being so averse to it. He however approves of it where it is practicable, illustrating its effects by the fact, that those who suffer from chronic ulcers in the throat, lose altogether the sensibility of these parts by frequent gargling and pencilling. He uses short curved needles, the blunt extremities of which are formed into hollow tubes for holding the pointed ends of the leaden wires used for the sutures. The lead wire should be of new drawn lead, as the old is brittle. The clots of blood are removed by a small piece of globular sponge, fixed in a

delicate forceps. The patient may take water in the mouth after the margins are excised, but not gargle, as this excoriates the abraded parts. When the cleft is not wide, and after the clots of blood have been thoroughly removed, the lead stitches, the upper one of which is to be inserted first, are to be twisted close together, so as to bring the edges of the excised cleft into perfect and intimate contact, so much so that the lead rings (i. e. sutures) become covered with the mucous membrane. But all this is not to be done until the whole number of sutures have been inserted, and which are only to be gradually approximated at first. Prof. Dieffenbach makes his excisions with the hook and bistoury. The *side incisions through the velum*, (and which we should say, ought to be made after excising the edges of the fissure, and inserting the sutures loose,) he deems of vast importance. One is made on each side the cleft, plunging the bistoury in half an inch distant from it, and half an inch distant also from either end of this cleft. The bistoury, with a sawing motion, is then carried directly upwards to the bony palate. Considerable blood flows, and the mouth must be washed frequently with cold water. The good effect of these incisions is seen immediately, the still-strained palate hangs down lax, like a damp curtain, and the wounds on the sides appear like two oval clefts, which would admit two fingers. The painful and straining sensation, which penetrates into the ears, also ceases immediately, and the air passes freely in and out through them. They are especially necessary and before finally tightening the wires and closing the cleft, when the fissure is wide and ascends high up; in such cases the lateral incisions have to be made through the palate, as near the cheek as possible. The patient must remain in bed, rather in a sitting than in a recumbent posture, and the mucus which collects in large quantities about the stitches, is to be frequently cleansed off by the sponge, as mentioned for removing the blood. Only water and mucilaginous drinks are to be given, as lemonade and acids oxidize the wire. On the third day the mouth may be washed with tepid water or elder tea, and on the fourth, the agglutination being ascertained to be complete, by probing it with the camel's-hair pencil, the first ligature may be removed, and on the fifth and sixth days the others. Frequently, in fact in many cases, M. Dieffenbach has thus succeeded in uniting the entire cleft. The shorter the cleft, the narrower it is, and in these, two or three stitches only will answer. If the stitches cut through and the cleft opens, they are to be speedily removed. Sometimes they suppurate, leaving only one. In that case they must also be removed without delay, except that one which is left for the support of a bridge. At the next operation, the edges being by this bridge found more approximated, will require an abrasion of a straw's width only. The preservation of union in the lower half is still more fortunate. If all the stitches cut through, the next operation should be deferred at least a year, as the scars will not have become soft till then. Frequently, M. Dieffenbach has succeeded completely in his subsequent operations. In a young lady, he met with entire success, though other surgeons had failed antecedently in three different attempts. The side incisions close without any aid from art. If after their closure any granulations protrude, they are to be touched with nitrate of silver. The closing up a cleft in the *hard or*

*bony palate* by the distinguished professor's method, is probably more easily described than accomplished. He first punches a hole through each edge of the cleft, and inserts a thick soft silver wire, which is to be drawn upon and twisted as close as it can be, after having first cut down upon, and then separated or cut through the palate bones on each side where they join the alveolar processes, by means of a thin, smooth, concave chisel. The flesh wound thus left soon cicatrizes, and an advantage is gained as to approximation of the cleft, by exciting its edges with the hot iron or tincture of cantharides, so as to produce suppuration and granulations upon them.

After the bony cleft is sufficiently closed, the cleft in the soft parts is to be sutured, and the side slits are to be made as before. The rest of the operation consists in covering over the bony cleft with mucous flaps, detached from each side, and drawn over and pressed into the cleft, and united at their free borders with fine leaden sutures. The abraded surface left by these flaps fills up with granulations, which prevent the mucous operculum from retracting again entirely, should some of its stitches cut through. It sometimes becomes necessary to cut entirely through a sound soft palate, in order to reach and extirpate or to cauterize steatomatous tumors, adherent to the posterior portion and to each side. This cleft is to be left open for free respiration till the cure is effected, and then reunited in the manner already described.

*Small openings* that remain in the palate after it has been stitched, or which come from ulcers, are found to be more effectually closed by *concentrated tincture of cantharides*, than by nitrate of silver, which latter Professor Dieffenbach says causes the loss of a layer of the organized mass, while the process of granulation which follows, produces an insufficient deposit of fibrine, so that the hole generally, actually increases in size. This, if accurately true, is a most important point to be remembered in all such apertures, since it is well known that they have hitherto been almost exclusively treated by cauterizations with the lapis infernalis. If these apertures are large and *oval*, their edges are to be regularly excised and brought together by a sufficient number of lead wire sutures. If we endeavor to cut *round* apertures into *oval* ones, there is risk, as the opening becomes larger if we fail. Their edges should be abraded however, and one or two stitches inserted, which are to be tightened after making a crescentiform incision through the palate on one side only of the hole, or if the hole is of considerable size, we should make one of these incisions on each side of it. The lateral incisions are to be stuffed with lint, which causes them to keep open, after which they gradually fill up with granulations. Small holes in the hard palate may also be healed up by excising their edges, also by means of tents of lint saturated with *concentrated tincture of cantharides*, kept in for an hour at a time and prevented from being swallowed by a strong thread attached to the tent and fastened outside the mouth. For large openings the professor recommends an artificial palate to *cover* the same, but not to project into it, and which instrument should itself be covered on its outside with a thin layer of gum elastic, and fastened by means of flat wire-beams to the cheek teeth. This does not prevent attempts at a radical cure by taking out the

palate daily, and moistening the borders of the instrument with the tincture of cantharides. In this manner he has frequently seen apertures that a finger could enter, finally closed up.

In all his operations on cleft palate, he gives the preference to lead wire sutures, because they can all be gradually tightened to the same degree so as to make uniform traction; whereas waxed silk and thread ligatures cannot be tightened uniformly, and some of the sutures will draw more than others and some even cut through. The hook and bistoury in making the excisions is far less irritating to the palate, and more commodious, he says, than the scissors. He says the suture is much more difficult, if we adopt M. Roux's mode and adjust that *before* making the side incisions. The side incisions also, even if we do not succeed, give us a better chance for success afterwards, for nature compels them to close up with new granulations, which of course in the same proportion diminishes the width of the cleft. M. Dieffenbach strongly condemns the cylinders used by Villemur's method to introduce the needles.

The wearing of any kind of obturator, that goes *entirely through* the aperture or the bony palate, as for example sponge or metallic substances, must necessarily defeat its own object in a measure, by enlarging the aperture itself. M. Dieffenbach has thus seen an aperture of the size of a quill increased so much as to admit the finger. There is no apparatus for clefts or holes in the soft palate, nor *imitation* velums and uvulas which can be employed without danger. In small apertures of the velum with callous edges, we may, until we operate, allow the patient to wear a double elastic plate, which represents a kind of caoutchouc *stud*, until it is practicable to operate. This is the invention of M. Dieffenbach. The intermediate portion must be so small in diameter as not to touch the edges. [Quere. Why could not this ingenious contrivance of M. Dieffenbach be used also for large apertures and wide fissures in the hard palate, and thus avoid the danger of increasing their diameter? T.]

In applying it the patient stands before a glass, and pinching the inner plate with a forceps inserts it through the hole, when it is immediately adjusted by its own elasticity. It is to be removed three or four times a week in order to cleanse it, and also to touch the edges of the opening with the tincture of cantharides should there be a prospect of diminishing the aperture by this means.

In *children*, where the cleft goes through the entire roof of the mouth, an apparatus made of a steel keel which goes over the head and has circular plates attached, which constantly press on both cheeks at once, will, if worn for some time, sensibly diminish the fissure by the compression it makes on the jaws.

In conclusion, to restore a destroyed velum is next to impossible; but in partial destruction of one side only we may make trial of the lateral incisions, excisions, and sutures, as above described. When through scrofulous ulcers or other affections, the *posterior surface of the velum has become agglutinated to the pharynx*, thus completely cutting off and isolating the nares from the throat, closing up the eustachian tube and causing deafness, it becomes exceedingly difficult to separate the parts. This is to be done by a cross incision, and

then detaching the soft parts from the posterior pharynx, and aiding this operation by a suitable spatula passed through the nose.

Mr. Fergusson of London. (see *British and Foreign Medical Review*, April, 1845, No. XXXVIII., pp. 415, 416,) by dissection of the cleft of the soft palate, and a careful inspection of its movements during life, comes to these conclusions: 1, that the flaps are slightly drawn upwards and to the sides, when the levator palati contracts; 2, that when the levator palati and palato-pharyngeus act strongly and together, the flaps are so forcibly drawn from the mesial gap, that they can scarcely be distinguished from the sides of the pharynx; 3, that the flaps are forced together, and the edges come into contact when the superior constrictor muscle contracts during the act of deglutition; 4, that the circumflex palati possesses but a feeble power over the flaps; and 5, that the fibres of the palato-glossus were very imperfectly developed in the specimen in his possession.

Based upon these principles, he proposes a *new process*, which he has in two instances applied with entire success. This consists of the division of those muscles of the palate, which have the effect of drawing the flaps from each other, and widening the gap between them when they contract, so that the stretched velum may be in a state of repose, and the joined edges may not be pulled asunder by any convulsive action of the parts during the process of union. That is, as an accessory to the operation, he advises a division of the *levator palati* and *palato-pharyngeus* muscles, and if requisite the *palato-glossus*. This is intended to effect *methodically*, by the application of *myotomy* to staphyloraphy, what probably is more thoroughly attained by M. Dieffenbach's large side-incisions through the velum.

Our countryman, Dr. Mütter, states that by the mode in which he has proceeded for staphyloraphy, he has succeeded in giving relief to all but two cases out of the *twenty-nine he has operated upon*. (*Report on the Operations for Fissure of the Palatine Vault*. By T. D. Mütter, M.D. 1843.) Dr. Mütter, like Dr. Mott, has found great advantage in the preparative familiarization of the parts to the instrument, finger, &c. So decided was this effect in one case, that Dr. Mütter could dispense with all means for keeping the jaws open or the tongue in place. He uses the hook, and seizes the lowest angle of one edge of the cleft first; then plunges a thin, narrow-bladed knife into this part, and like Dieffenbach, excises rapidly upwards to the bone. The strip is then drawn tense and detached downwards. His needle is small and curved, and fixed in Physick's forceps, and the thread is waxed silk. Unlike Dieffenbach, Dr. Mütter puts the lowest suture in first. We have noted the principal points in which the steps of Dr. Mütter's process differs from that of others. He has never met with any serious accidents. If *severe griping* should follow the operation, and which symptom he attributes to the swallowing of blood, he recommends as the best resource, injections to be repeated every hour till the blood is brought away, or if requisite an anodyne enema.

Sir Philip Crampton's process differs from most others in two peculiarities, (*Dublin Journal of Med. Science*, vol. XXII., 1843, p. 320, &c.): 1, in securing the ligatures, which are of the ordinary

kind, by passing down upon them, as suggested by Mr. Maclean of Dublin, a small metallic bead, which, when it reaches the edges of the cleft and has drawn them together to the degree required, is compressed by a forceps, and thus makes a knot unnecessary; 2, in discarding the starvation system of some, and allowing the patient to eat all kinds of lubricating soft food, as jellies, custards, soups, &c. He had at the period mentioned performed the operation by his process in two cases, one a boy aged 12, and also on a young lady aged 16, in both with entire success.

At the sitting of the Paris Royal Academy of Sciences, March 17, 1845, (see *Arch. Gén. de Méd.*, 4e ser., t. VII., April, 1845, p. 507,) the commission, composed of MM. Pariset, Roux and Velpeau, reported in the most favorable terms of a new *artificial substitute* for perforations through the vault of the palate, lately invented by M. Stevens. This obturator is remarkable for its nice adaptation to the parts, without the aid of springs, clasps or hooks; also for its lightness, delicacy and strength, and the ease with which it may be adjusted or removed. In the case to which it was applied, a superior officer of the army in Africa, there was a large opening from the nasal fossæ into the buccal cavity, causing all the usual annoyances as to deglutition, articulation, &c., all of which were perfectly removed by the apparatus. T.]

## CHAPTER IV.

### THE OLFACTORY APPARATUS.

#### ARTICLE I.—NASAL FOSSÆ.

##### § I.—*Foreign Bodies.*

A. Foreign bodies of all kinds are found in the nares. Khern (Planque, *Bibl. Méd.*, t. XXI., p. 568,) saw there a *calculus* of the size of a pea, and which was ejected by sneezing, after the continuance, for a year and a half, of pains between the two eyes. In another case (*Gaz. Salut.*, 1768, No. IV., p. 3,) the concretion was almost as large as a nut. M. Graefe speaks of a calculus that had formed upon a cherry as its nucleus; also of another in a gouty person, which was friable. A nasal calculus mentioned by Wepfer (Jourdain, *Mal. de la Bouche*, t. I., p. 519, obs. 19,) and which was an inch long, rested upon the root of the only tooth which the patient had remaining. It is to be remarked, also, that stones have in this manner been very frequently ejected from the nose. A girl ejected, first, seven stones of the size of a pea, some of which were of talc and others of granite; second, four other fragments of the size of a filbert and irregular in shape; third, another stone; fourth, three more stones; and fifth, three small bladders, according to the report of a curate (*Gaz. Salut.*, 1761, No. X., p. 3,) who was the dupe of this personage. Two small girls who were brought to Deschamps (*Tr. de la Taille*, t. II.,

p. 131, obs. 47) by their mother, one seven years of age and the other eight, pretended to have been throwing out stones from their nose and ears during the space of several months; some of the stones exhibited to the surgeon left him in no doubt as to the deception; one was a piece of wall plaster, the other a very small flint; the children confessed the trick.

B. A *pea* had assumed in the right nostril the appearance of a polypus; Renard (*Gaz. Salut.*, No. 51, 1761, p. 4,) extracted it with the tenaculum in presence of five of his confreres, who had been deceived by it. Dumoustier mentions two dry peas which had been introduced into and had become swollen in the nose during the space of two days. It became necessary to extract them in fragments, by means of a gimlet, (*Obs. et Reflex. sur quelques Corps étrang.* etc., Strasb., 1810, p. 8, obs. 3.) Meckren (*Obs. Méd. Chir.*, chap. 14,) even speaks of a polypous excrescence containing within it a fragment of wood, which a child three years of age had secretly thrust up its nose, and which had been the cause of the suppuration and excrescence. An *earwig* which got into the nose and occasioned there, according to Sandifort, (*Exercit. Acad.*, 1788; *Gaz. Salut.*, 1786, No. 51, p. 83,) excruciating pains, was expelled during fumigation with tepid water, and was followed by the evacuation of a fetid pus. A *leech*, which had been swallowed and become attached to the nasal fossæ in the druggist Lalouette, (*Rec. de Mém. de Méd.-Chir. et Pharm. Mil.*, t. X., p. 406,) kept up in this manner an epistaxis during the space of three weeks. Bleeding, astringents and topical applications had no effect; a tampon of lint, wet with eau de Ravel, succeeded no better. The blood began to flow again when it was taken away in the morning; the patient finally blew his nose and the leech was expelled. Thos. Etbrun (*Gaz. de Méd.*, p. 288, t. II., 1761,) also mentions that a leech, whose head and tail had become attached to the posterior cavities of the nose, produced an epistaxis and spitting of blood, during the space of from 18 to 20 days, which resisted every remedy and several bleedings; the inhalation of saline vapor through the nose caused the leech to drop off behind the uvula, where it was seized with the forceps.

C. A *cherry nut*, which had caused an obstinate pain in the head, spontaneously came out through the mouth, after having remained a long time in the nose. A similar fact is mentioned by Verduc, (*Tr. d'Oper.*, p. 229.) A young lady in this manner ejected calculi of the size and shape of dates, according to Bartholin, (Planque, *Bibl. Méd.*, t. XVIII., p. 97,) and of the dimensions and length of the finger, according to Water, (*Coll. Thèses de Haller*, t. II., p. 230.) A peasant girl had a stone in her right nostril, which shut it entirely up and occasioned an extensive tumefaction of the nose. A fetid sanies continued to ooze out from thence during the space of 17 years; and the septum had become pushed towards the right. M. Rittmeister (*Journ. d'Huffeland*, 1817, et *Bibl. Méd.*, t. 62, No. 185, Decembr.) succeeded in extracting the stone from it by means of the forceps. It weighed two gros and a half, and was an inch in diameter.

D. M. Champion has found the best means of extracting such bodies to be the *black pin* with two branches, or the hair pin fastened upon a cork. I have procured the same success with an ordinary

*probe*, curved into a hook near its blunt point. Madame D. called on me, in great trepidation, with her child, three years of age, who had just introduced into its right nostril a flint which could not be extracted. It was a smooth stone in the form of a sugar plum, and of the size of a large almond. The small hook readily relieved the little girl of the difficulty. We may in this manner remove peas and the pits of fruit and other uniform bodies; if the substances were stems, or angular or adherent bodies, the forceps would be preferable. For living animals and insects it would be necessary to have recourse to injections of various kinds of liquids. Making the patient sneeze and blow his nose also is an auxiliary means which he is not to neglect.

[*Foreign bodies—Nostril.*—Dr. P. F. Eve of Georgia extracted from the right posterior nares, by means of his forefinger introduced into the mouth, a tailor's thimble which a little girl aged six years had got up her nose while playing with it, and where it had remained deeply impacted for two weeks, without however producing much inconvenience, (*Amer. Journ. of the Med. Sc.*, Philad., 1839, vol. XXV., p. 494.) T.]

## § II.—*Hemorrhage and Tamponing.*

Whether the bleeding which comes from the nose be the result of a traumatic lesion or sanguineous congestion, as soon as it yields no longer to revulsives, cold topical applications, styptics and astringents, or that its duration and abundance give room for anxiety, the surgeon should without hesitation have recourse to the tamponing of the nasal fossæ.

A. This operation, which is as simple as it is easy, is performed in the following manner: We first prepare a roll of lint sufficiently large to shut up the posterior opening of the nostril, around the middle of which is tied a double waxed-thread, and to this also a long common thread. Other rolls, which are of smaller size or merely made with coarse lint, are also to be prepared beforehand. The operator passes into the pharynx, through the bleeding nostril, either a gum elastic catheter or catgut, a leaden or silver wire, or even a stem of flexible wood, or if it is practicable *Bellocq's* sound, and proceeds in such manner as to bring to the outside, through the mouth, the extremity of one of these objects, either by seizing it at the bottom of the throat with one or both fingers, or by pushing the spring of the sound, if it is this that he employs. Then attaching the double thread to this extremity, he draws upon it in order to bring the roll of lint into the posterior fauces, carrying with it the single thread. He then removes the guiding instrument, which has now become superfluous: again draws upon the plug of lint and forcibly secures it from behind forwards in the diseased nostril, which is thus found closed up posteriorly; separates the two extremities of the ligature which come out through the nose; passes between them, from below upwards and before backwards, the other rolls or coarse lint, until the front portion of the nasal cavity is entirely filled up by them; afterwards crosses the threads as if for the purpose of knotting them, and tightens them with all the force that he judges neces-

sary upon this last mentioned tampon, in such manner as to push it backwards, at the same time that he acts again upon the other with equal force in order to bring it forwards. By this means we may easily fill up the nostril with lint, close up at least its two openings, and present an insurmountable obstacle to the hemorrhage. The two ends of the thread which come out of the mouth and nose are to be raised up and attached to the cheek, or fastened to the night-cap of the patient, until the period arrives when the dressing is to be removed. It is at this time only that the single thread is to perform its office, unless the surgeon has been forced to withdraw and to replace the posterior nasal tampon before definitively adjusting it previous to removing the whole, which should never be done before the complete cessation of the *molimen hemorrhagicum*, or seldom, at least, before the second or third day. He then divides or unties the anterior knot and withdraws through the nose, by means of the forceps, all the lint, with the exception of the first plug, which is removed from the pharynx, by the mouth, by making tractions upon the posterior thread.

B. We are indebted to *M. Martin Saint-Ange* (Lapeyroux, *Thèse*, No. 314, Paris, 1836,) for a process still more convenient than the preceding. A canula opening at one end into a small sac, and provided upon the side of its other extremity with a faucet, which may be opened or shut at pleasure, composes the entire instrument, which the author denominates a *rhinobion*. It is introduced, shut up, into the nose as far as to the pharynx. It is then opened, and air blown or water injected through the canula into the little sac; it is then shut up, and the distended sac drawn towards us from behind forwards, and the whole fastened upon a tampon of lint in front of the nostril. This instrument, which Bell and M. Miquel-d'Amboise (*Ibid.*) had mentioned, has also succeeded upon the patients treated by M. Martin Solon (*Bull. de Therap.*, t. XII., p. 20,) and the inventor.

[*Epistaxis*.—M. Négrier (*Arch. Gén.*, 4e sér., t. II., p. 354, 355) recommends as a curative means in nasal hemorrhages, to keep the two arms raised up above the head, while the nostrils are to be held shut. He has known two persons who were in the practice of this method, to stop a bleeding of the nose which they were liable to. The curative action is ascribed by him to the retardation which is thereby effected in the return of blood to the head. T.]

### § III.—*Polypi of the Nose.*

Polypi of the nose may be cured by exsiccation, cauterization, the seton, excision, tearing them out, and the ligature; but these different therapeutical methods are far from being always equally efficacious or deserving the same degree of confidence.

A. *Exsiccation*, for example, is evidently applicable only to mucous polypi taken at their commencement; it is even doubtful then if the results which it procures will be very satisfactory. Moreover, at the present day it is only occasionally employed, either subsequently to, or as an auxiliary to the excision or tearing out of the polypus. Notwithstanding what Aetius, Alex de Tralles and Actuarius, and a

multitude of ancient authors have said of the powder of *Teucrium marum*, and the apparent success which M. Mayer states he has had with it, this does not, in my opinion, appear calculated to throw any doubt upon this judgment. I would say the same of compression by means of a kind of tamponing eulogized by M. Lamauve, (*Soc. Méd. de Montpellier*, t. IV., p. 129,) after having made trial of it in one instance with success.

B. *Cauterization* is somewhat more worthy of attention, and I should not be surprised if the future should reverse the unfavorable verdict which the moderns have given on it. Hippocrates, who had already praised it, used the hot iron by preference. Arsenic, and acetate and sulphate of copper, were, according to Galen, preferred by Philoxenes, while Antipater and Masa also made use of vermilion of Sinape. Sandarach, pimento, burnt lead, the root of the ranunculus, quick-lime, and potash, lauded by Archigenes, S. Largus and P. de Bairo, have since been replaced by butter of antimony, (which Garengeot used only after he had protected the sound parts by placing a plaster between the polypus and corresponding wall of the nose,) nitrate of mercury, nitric and sulphuric acids, or the nitrate of silver. These different catheterics were applied to the disease by means of meches, tents, or rolls of lint, pieces of sheet-lead, metallic tubes, &c., in order to touch its prominent part and destroy it by degrees. Afterwards they substituted for these, injections of lime-water, solutions of alum or vitriol, astringent or styptic decoctions; finally, the whole array of desiccative medicaments; and the history of medicine shows that many radical cures of polypus have in fact been obtained in this manner.

I. *Process of Jensch*.—In 1827 M. Wagner published some remarkable cases which, if authentic, are worthy of attracting public attention. He succeeded in discovering the secret of a German empiric named *Jensch*, who had acquired in his province the reputation of readily curing the most obstinate polypi. Having gained possession of this secret nostrum, which is nothing else than a melange of sulphuric acid, butter of antimony and nitrate of silver, M. Wagner (*Bull. de Fér.*, t. XVI., p. 96,) was desirous of putting it to the test by following out exactly, moreover, the rules laid down by the charlatan. Now, according to his representation, its effects have been almost miraculous. The following is the process which he gives: A metallic stem, in the form of a long pin, and having a head of the size of a large pea, is the only instrument required. After having placed upon the head a layer of caustic of greater or less thickness, it is directed upon the projecting portion of the polypus, and this application is repeated from two to five times. The operation is daily renewed until the tumor falls or is destroyed. An injection of alum is thrown up an hour before and an hour after the cauterization. When the principal mass is detached, we confine ourselves to touching the remainder with lapis infernalis. The injection should be continued during the space of two months; and in order to restore to the sense of smell any defect that it may have sustained, we prescribe to the patient powder of *napeta* (*Teucrium verum*) in the form of tobacco. Moreover, I see no objection to making trial of this treatment, at least in timid patients, or where the polypus, being found as difficult to extract as it is to tie, is greater in its breadth than its pro-

truding part. It would not, moreover, be the first time that ignorance and gross charlatanism have suggested the idea of an advantageous medication to the art of treating diseases methodically.

II. *The actual cautery*, which naturally inspires somewhat more confidence than the potential cautery, and which, according to the Arabic physicians, it suffices to apply on the forehead to prevent the reproduction of polypi; which has been so warmly extolled by Roland of Parma, who applied it to the disease through a canula; by D. Scacchi and P. de Marchettis, who had the courage to repeat this application successively for twenty days; by Purmann, who succeeded in three instances by means of an iron wire heated to a red heat; and by Richter and Acrel, who were careful to wrap the conducting tube in wet linen, the better to protect the surrounding tissues, is nevertheless at the present day almost totally abandoned. It is only occasionally that we may still have recourse to it in rare instances, as for destroying some of the remains of the polypus which have been left after the other operations, to remedy the hemorrhage which sometimes succeeds to its extraction, or to attack organized (*vivaces*) or malignant polypi. None of these cases even absolutely demand it. In the first case, escharotics, which are less alarming to patients, are justly preferred to it. Tamponing replaces it perfectly well in the second case. In the third case, the knife, hot iron, and other applications, are almost equally dangerous. The kind of polypi, which bleeds upon the slightest touch, frequently even without being touched, and which produce a remarkable change in the features of the patient, and are accompanied with lancinating pains, do not in fact yield to any remedy, and form a true *noli me tangere*.

III. *Appreciation.*—The operation, moreover, is easy, so long as the polypus is not situated too deep within. During the space of some days the anterior orifice of the nose is to be dilated if the cautery is to penetrate through it. A *speculum nasi* afterwards enables us to ascertain precisely the situation of the tumor. After these preliminaries, the surgeon takes a canula, attached at an angle at its base to a handle, or to the ends of a species of forceps, unless he prefers making use of a simple tube secured by a dressing forceps; wraps it in wet linen, and directs it upon the polypus, which may then be burnt by means of the reed or olive-shaped cautery heated to a white heat. Through the mouth, that is to say for polypi in the posterior fauces, it would, in most cases, be impossible to use this means, which, even in other instances, is frequently followed by intense cephalalgia and very severe cerebral accidents, as Sabatier has repeatedly observed.

C. *The seton* is a resource of another kind. Three distinct objects, might, if necessary, be obtained by this.

I. *The packthread arranged with knots*, first proposed by Paul or rather by Rhazes, afterwards by Avicenna, and especially by Brunus, in order to *saw through* the polypus, is a species of seton constructed with considerable ingenuity, but which must act, to say the least of it, as much on the Schneiderian membrane as on the morbid tumor. Nor is the *silver wire*, surrounded with a brass wire running round it spirally and sustained by two handles, the one fixed and the other immovable, as recommended by Levret, in place of the seton of the ancients, found any longer in practice.

II. The idea of *Le Dran* was more natural. This surgeon, by passing a hook through the nostrils, in order to seize a meche of cotton introduced into the pharynx by the forefinger, or by inserting a catgut, which he brought to the exterior through the mouth, in order to attach this meche to it and to draw it afterwards from behind forwards into the nasal fossa, succeeded in destroying a polypus, many of the roots of which at first had escaped from him. It was then easy for him to introduce daily into the nose a roll of dry lint at first, to remove the foreign matters; and in the second place rolls of lint saturated with digestive or cathartic ointment, calculated to favor the separation of fragments from the polypus, and to cleanse the wound. It was also for this purpose and to obtain this object that Hippocrates and Loyseau (*Observat. de Chir.*, &c., p. 67), and some others have also extolled the seton.

III. *Goulard*, with the intention of simplifying the process of *Le Dran*, has in reality only complicated it still more. The hook shaped like the nasal fossæ, which he prescribes instead of the catgut, and the fork, which enabled him to introduce the seton behind the velum palati, instead of using the finger, are evidently less convenient. After all, at the present day we introduce the seton through the nostrils in the same way as for tamponing its cavities. It is a method the advantages of which consist in enabling us to introduce medicated substances upon any point whatever of the nasal fossæ.

D. *Excision* appears to go back as far as to the time of Hippocrates, or at least to Celsus, who mentions a species of cutting plate (*spatha*), by which it was practised. Paul cut out the polypus by means of his *spathapolyptica*, one of the extremities of which had attached to it a chisel, and tore out the rest by a *polypoxista*. Abu'l Kasem commenced by depressing the tumor by means of a hook, in order afterwards to excise it with a cutting instrument. Others, Scacchi, for example, operated with the simple bistoury, or, like Hutten, with a species of syringotome, or again after the manner of Nessi, with a curved and blunt-pointed bistoury. J. Fabricius censures these instruments and warmly extols a kind of forceps in the shape of a double cutting spoon, which M. A. Severin accuses him of having borrowed from Nicollini, without acknowledging it; an instrument which Glandorp, V. Horne and Solingen have successively modified, and which Dionis, Percy and B. Bell have considered should not be entirely rejected from practice. *Le Dran*, Manne and Levret, who also under some circumstances excise polypi, employed no other instruments than the ordinary bistoury or curved scissors. M. Wathely, however, has in latter times returned to the use of the syringotome, that is to say, of a bistoury prolonged into the beak of a sound, concave on its cutting edge and enclosed in a sheath, in which it can be readily made to glide either towards its point or handle. When the polypus possesses a certain degree of solidity, and approximates very near to the exterior or to the pharynx, there is no doubt that by the process of Abu'l Kasem with a bistoury; or better still, the common scissors or those that are curved flatwise, we may succeed very frequently in removing it; and that the cutting forceps of J. Fabricius may also attain this object in the depth of the nasal fossæ, under certain circumstances. Nevertheless excision is an uncertain method,

which almost always requires to be assisted by one of the preceding processes if we do not wish to see the disease repullulate, and one which consequently ought not to have the preference but in certain exceptional cases.

E. *The tearing out of the polypus* (arrachement), which has been generally substituted for excision, is a method not less ancient and in other respects very important. It is doubtless from having confounded the cutting pliers with the ordinary pliers, that the moderns have ascribed the first suggestion of it to Paré, or rather to F. ab Aquapendente. It is found distinctly mentioned in the works that Sprengel ascribes to Thessalus and to Dracon, the son of Hippocrates. There existed, even at that epoch, two modes of performing it. In one there was introduced by the nose a piece of sponge firmly tied and fastened by four threads; after which, by means of a long needle, they endeavored to conduct these threads into the posterior fauces, and to make traction above them by means of a forked instrument, and thus tear out the polypus. The other consisted in first tying the tumor with a catgut surrounded with a thread, and in extracting it afterwards through the pharynx. Paul and Rhazes also speak of this last process as one in common use.

I. Brunus recommends that we should remove the fleshy excrescence by means of a hook, and G. de Salicet had already advised the forceps. Aranzi, who had contrived a kind that are very long, found great advantage in directing the light so that it should fall into the nose through a hole in the window, or through a glass globe filled with water. Whatever may have been said in praise of hooks, by Job-a-Meckren, it is nevertheless to Dionis that we are indebted for the first circumstantial details upon the subject of employing them methodically. Since adopted by almost all practitioners, they have been modified by Sharpe, who sometimes employed such as were curved; by B. Bell, who pierced, or made an aperture through their branches, and by Richter, who for large sized polypi invented a kind whose branches could be adjusted separately, like those of the [uterine] forceps. The straight forceps are the best wherever the situation of the tumor allows of their application. By making them turn upon their axis, we act upon the polypus with a degree of force which cannot be applied with the curved forceps. These last are reserved for tumors which we wish to attack through the throat and bring out by the mouth. As to the *shifting forceps*, they possess a decided advantage, when the mass to be extracted is too voluminous for the common hooks to embrace it with facility in the depth of the nasal fossæ. Whatever, moreover, may be their dimensions or general form, it is important that their extremities should be pierced, or concave upon their inner side like a spoon, and provided with small points, called wolves' teeth, in order that they may have a firmer grip. It is also advisable to give them as much solidity as possible; otherwise we should very often incur the risk of their bending.

II. The tearing out of a polypus, moreover, after the manner of the ancients, has never been entirely laid aside. *Theden*, for example, first introduced a ligature upon the pedicle of the polypus, by means of a forceps, which formed by their union at the point a ring dentated upon its convexity, and pierced with an eye at each of its

free extremities ; after which he made use of his thread to exercise tractions upon, and to tear out the tumor. Although Vogel has used with success the forceps of Theden, M. Cooper, who, when he can, also tears out polypi by means of a ligature, has nevertheless deemed it advisable to reject their employment, and no one at the present day would venture to maintain that they are indispensable. In admitting that this kind of extraction may have, as M. Cooper alleges, the advantage of incurring less risk of hemorrhage, and of removing at the same time the entire root of the polypus, and the fibro-mucous membrane which has given origin to it, it would nevertheless possess the serious inconvenience of exacting two operations in place of one, of being applicable only to hard, pediculated polypi, and of not being susceptible of application but with difficulty in the depth of the nostrils.

III. When the tumor does not exceed the size of a nut, and that it is solid, and without a pedicle of too great a thickness, *Morand* has been indebted for some successful results to the following process :—The two forefingers are introduced into the nose, one in front, the other behind, and as far as the polypus, upon which traction is then made by pushing it alternately towards the pharynx and the face, in order that it may be finally detached and forced to come out by the passage which presents to it the least degree of resistance. This is a process, moreover, which, after the manner of Dupuytren, it would be advisable to combine with the employment of hooks. There can be no doubt, in fact, that by pressing with the finger through the pharyngeal opening of the nasal fossa upon the tumor, we should be able to effect its extraction with more certainty and facility by means of the forceps, which draw upon it in the opposite direction.

IV. *Operative Process.*—This mode by *arrachement* requires no preparation, unless we should think proper to imitate G. de Salicet, by gradually enlarging the anterior opening of the nares by means of a sponge, or any other dilating means. Cold water, oxycrat, one or more basins, an aleze and napkins, lint, and all the articles necessary for tamponing the nasal fossæ, an erigne, scissors, a blunt-pointed and ordinary bistoury, dressing forceps, the forceps of Museux and several pairs of polypus forceps, as they may be required, should be arranged upon a table or a broad board. It is also advisable to have several rolls of lint sprinkled with colophane, and even one or two cauteries in case of obstinate hemorrhage.

a. The patient with an aleze around him, and seated in front of a window with his head supported by an assistant, should have his hands free if he is an adult, in order that he may be enabled to use the gargle at pleasure ; or his hands should be surrounded and covered by the aleze, on the contrary, if he is a child. The operator being placed in front, and standing up, introduces his hooks through the orifice of the nose ; recognizes with this instrument the precise seat of the polypus, which he seizes as near as possible to the pedicle, while taking care also to embrace it to a very great extent ; draws it gently towards him ; seizes it a little higher up, if it elongates, with a second forceps, without abandoning the first ; then with a third, if he

is still fearful of tearing it without removing it by the root, and thus endeavors to extract it entire at the first operation.

b. When the tumor, from being situated too far within, or not sufficiently distensible to enable us to bring it to the exterior without having lacerated it, it is more advisable, as soon as we have seized hold of it, to turn the forceps upon itself two or three times without oscillating it, while at the same time we draw upon it until the polypus yields and is detached. During these efforts the instrument is held by means of its rings with the right hand, and near its entablure with the left, in order that we may direct its movements better, make it act in certain cases in the manner of a lever of the first kind, and to incline its spoon-shaped grip with all the force necessary, upwards, inwards, or outwards.

c. If the whole of the tumor is not extirpated at first, or if there are several of them, we immediately recommence, and always in the same manner, until we are certain that there is no longer any foreign body in the nasal fossa. In this respect, when we are desirous of knowing the exact condition of things, and that the eye no longer affords us any assistance, it suffices to make the patient blow out with force while we hold the sound nostril shut. So long as the air finds difficulty in passing we may be satisfied that some portions of the polypus have escaped the action of the instruments. If on the contrary nothing interrupts it, and it comes in freely to the respiratory passages with a *clear and full* (*nette et franc*) sound, it is useless to make any further researches and the operation is terminated.

V. *Appreciation.*—Mucous polypi are too soft and adapt themselves too readily to the parts which surround them, for the narrowness of the nasal opening to interfere seriously with their extraction. With hard polypi it is different; the irregularities which they are covered with in order to adapt themselves to the form of the passages, the prolongations that they sometimes send off, either backwards or forwards or into the maxillary sinus, or, as I have seen in one instance, into the zygomatic fossa through the spheno-palatine foramina, two other instances of which have also been seen, one by M. Blandin and one by M. Cazenave, (*Bull. Méd. de Bordeaux*, p. 25,) render it in certain circumstances extremely difficult to draw them to the exterior. Inasmuch as the bones in the body of the nostrils do not present any great degree of resistance to them, they depress them, push the septum in one direction, separate the turbinated and ethmoid bones in another, and very easily depress the vault of the palate; while posteriorly the pterygoid process, the body of the sphenoid and the thick border of the vomer present a much more considerable resistance to them, while in front the ascending process of the maxillary bone also presents an obstacle to them for a greater or less length of time.

a. They are especially arrested by the circle or fibro-cartilaginous border of the facial opening of the nostril. Owing to its great elasticity and its want of distensibility this circle has a constant tendency to return to its natural limits, and makes infinitely greater resistance than the bones to the force directed upon it. If then it should appear that the extraction of a polypus of somewhat large dimensions would

be thereby rendered too difficult, we ought, rather than have recourse to the dilatation of G. de Salicet, to slit up the ala of the nose from its free border as high as to the triangular cartilage, as Dupuytren recommends, as I myself have done in two instances, and as M. Serre (*Compt. Rend. de la Clin. de Montpellier*, 1837) has also practised with success.

b. *When the tumor extends beyond the posterior opening of the nasal fossa*, it is rarely practicable to extract it entire through the nose. It is under such circumstances that the curved hooks become indispensable for seizing it through the pharynx, as has been done also by M. Bermond (*Bull. Méd. du Midi; Gaz. Méd.*, 1838, p. 442) with success. If in this position it should have acquired a great volume, or if in consequence of any particular arrangement it had crowded downwards and forwards the posterior half of the palatine vault to so great a degree as to contract the arches of the palate, the method of Maune or of Nessi, indicated by Hippocrates, Guy de Chauliac or Garengéot, adopted in practice by Loyseau, (*Obs. de Méd. et de Chir.*, p. 66,) Petit and Hulterus, (Percy, *Mém. sur les Ciseaux*, p. 70,) and which consists in *slitting open* from above downwards the *velum palati* with a curved bistoury, would not be unworthy of adoption. Heuermann and Morand had every reason to be satisfied with it; and I myself have tested its value in a similar case. The objections that Schumacher makes to it prove only that it was not indispensable in the case he mentions. It is literally a *débridement* which is effected without any fear of wounding an artery of any dimensions. The reunion afterwards took place spontaneously in one of the patients upon whom I operated. The polypus, which may be then embraced and torn out, if not entire, at least in fragments, by means of the forceps or fingers, might also be excised with the curved scissors or the cutting hooks of M. A. Severin.

c. Finally, there are cases where it is necessary that these different operations should be united and skilfully combined, where after having extracted a large portion of the tumor through the nose, and another through the pharynx, as is seen in the example that M. Chaumet has given, whether we have detached it or not in front or behind, enough still remains to which the process by *ébralement* of Morand might also become applicable.

d. In whatever manner it is performed, the patient should be permitted from time to time to wash out his mouth and nose by furnishing to him simple cold water or vinegar and water. Should the hemorrhage become too abundant, every manipulation should cease, and further attempts put off to an interval of some days. When however it does not cease spontaneously, it is arrested by tamponing, which renders the application of caustics or hot iron almost always unnecessary. Nor should we proceed so far as this even until we have unavailingly made use of inhalations of the eau de Rabel, or a solution of alum or some other styptic.

VI. *Torsion*.—The extraction of polypi, and especially of mucous polypi, is almost always effected by torsion. The surgeon having embraced the tumor well and properly adjusted the hook or forceps, turns it while drawing upon it as if upon its axis, and thus incurs less

risk of having the instrument relax its hold, and the polypus crushed and broken into fragments before yielding at its root.

VII. *Subsequent Treatment.*—The tearing out of polypi is rarely followed by serious accidents. It is rare that any fever supervenes, or that the patients are under the necessity of restricting themselves to diet during the space of two or three days. It is, nevertheless, a method which is far from always succeeding, or of being susceptible of employment under all circumstances without inconvenience. It is particularly well adapted to mucous and fibrous polypi, which have one root only, and to all those whose base is not extended over too large a surface, or which, in a word, it is practicable to extract entire. The sarcomatous polypi, whose cancerous degeneration commences at the projecting part, would also be applicable to it if, as Dupuytren alleges, we could distinguish them from the others before proceeding to the operation; but according to Boyer, it would in other cases only hasten the development of the accidents, and lead to dangerous transformations. Here also, more than in any other cases, the operator ought to recollect the anatomical arrangement of the nasal cavities, in order that he may not pinch up and tear out for polypi the turbinated bones which are external to it, nor shatter the septum which is on its inside, nor the cribriform plate of the ethmoid which is above, nor mistake a simple engorgement of the mucous membrane, or some deviation in the bones, for an abnormal production, nor fail at any stage of the operation in always guiding the forceps in a proper direction, nor be ignorant also that there may exist in the nose tumors, whose root is in the frontal sinuses, as in the patient operated on by M. Hoffman, or in the maxillary sinus, in the interior even of the cranium, or in the pterygo-maxillary fossa for example, as in the patient mentioned by M. del Græco, and in whom the supra-maxillary nerve was transformed into five enormous masses of a polypoid appearance. In a patient of M. Janson, (*Compt. Rend. de l'Hôtel Dieu de Lyon*, p. 64, 1822,) the polypus, which occupied the two nares and the maxillary sinus, made its appearance in the mouth through an opening in the dental arcade, partially issued through the ulcerated lachrymal sac, projected into the orbitar cavity, from whence it had thrust out the globe of the eye upon the cheek, and obstructed the pharynx to such degree that it became immediately necessary to separate certain portions of it by means of the ligature and knife in order to prevent suffocation. In a boy 16 years of age in whom I had removed one lobe of it, and who died of small-pox, the polypus protruded at the same time outside of the nose, into the pharynx, into the cheek through the sinus maxillare, into the orbit and temporal fossa, and also into the cranium, the base of which had become softened and worn away by it.

F. *Ligature.*—The ligature, like most of the preceding methods, goes back to the remotest antiquity. The Greeks and Arabs, nevertheless, rarely proposed it, except as an auxiliary to excision or arrachement. We have to come down as far as to the 16th and 17th centuries before we find it clearly described and formally indicated. Fallopius applied it by means of a brass-wire, a noose of which he directed around the polypus by means of a silver canula. F. de Hilden has not described his process. Glandorp, who paid

particular attention to it, applied the ligature by means of a kind of needle shaped like a hook, and having an eye near its point, which was furnished with a silk thread. It was in the course of the last century especially, that it became the subject of a multitude of investigations and modifications.

I. *First process of Levret.*—Thus Levret proposes to conduct a silver wire by means of a sound upon the root of the tumor, to make its two extremities afterwards pass through a double canula, in order to twist them by turning it on its axis, after having fastened them to the rings which it has on its free extremity. Pallucci, in place of two tubes, soldered together at their sides in form of a double sound, states that he had invented a simple canula like that of Fallopius, but which was divided into two portions near its nasal extremity, by a small septum. Levret himself made use of this instrument, and published an account of it before Pallucci spoke of it. It is neither perceptibly more or less convenient than the preceding, of which it is to be considered as a simple modification. The same may be said of the instruments of Nessi, Hunter and Kluge.

II. *Second Process.*—Levret not being enabled to reach polypus in the posterior nares with his double canula, contrived for this purpose a species of ring-forceps or ligature-holding forceps, with long branches slightly curved, dilated at their extremity, and hollowed out, but which surgeons have not adopted any more than they have those of Theden, which undoubtedly suggested them.

III. *Process of Brasdor.*—The difficult point in the first process of Levret, is to secure the polypus in the middle of the noose, which the metallic tube conducts to it. Brasdor proposed to remedy this inconvenience by making use of a Coupelle silver wire doubled so as to form a noose, drawn in the same way that plugs of lint are from behind forward, when we wish to tampon the nasal fossæ. When the two extremities of this ligature are once brought out through the nose, the surgeon seizes them with one hand, draws them gently towards him, while with two fingers of the other hand introduced into the pharynx, he endeavors to pass its noose upon the root of the polypus, then introduces them into a knot-tightener, and immediately proceeds to the strangulation of the tumor. A simple thread is moreover fixed upon the middle portion of the silver wire, and left free in the mouth, in order to be enabled to draw the ligature backwards, and to replace it should it not be found at first to be properly adjusted. This, it must be confessed, is a real improvement; but as we cannot tighten the metallic ligatures but by twisting them upon themselves, and as they consequently frequently break before having cut through the pedicle of the tumor, many persons have always preferred to these the use of ligatures of hemp, flax or silk. The only advantage, moreover, which can be claimed for them is that they form a noose, which easily keeps itself open without bending, and which consequently is better calculated than that of soft ligatures to glide upon the root of the polypus.

IV. *Process of Desault.*—Desault, reasoning upon this hypothesis, at first confined himself to adjusting a ligature of thread in place of the silver wire used by Brasdor. Subsequently, in order to obviate the difficulty of forcing the tumor to become embraced in the noose

of a ligature so pliant, he adopted another course. His last process is performed by means of three distinct instruments: first, a *canula*, slightly curved, terminated in a dilatation, (*en larme*), and having a lateral ring at its other extremity; secondly, a stem of iron or steel, which is a sort of *knot-holder*, which is shut up, and which glides without difficulty into a second canula, and when it is open represents a forceps, while when shut its beak forms a true ring; third, a *knot-tightener*, which is another metallic stem, one of the extremities of which, bent at a right angle upon its axis, has upon it a rounded opening, and the other of which forms a cleft plate. One of the extremities of the thread is attached to the ring of the canula, which it also has passed through. The other is then passed into the ring of the ligature-holding forceps, which is immediately shut up by drawing it into its sheath. The surgeon then directs these two instruments together upon the polypus, and even a little beyond it, endeavors to apply them above or below, or to the right or to the left of the pedicle of the tumor, seizes the knot-holder with the left hand and stops it at this point, while with the other hand he causes the canula to pass around the whole circumference of the polypus, and brings it to the point diametrically opposite, in order to embrace the pedicle accurately; glides once or twice, one around the other, the canula and the knot-holder, in order to transform the noose of the thread into a true circle; withdraws these instruments; leaves the ligature in its place; passes its extremities into the ring of the knot-tightener, which he pushes backwards with more or less force, with the view of strangulating the morbid mass; fastens the extremity of the ligature upon the cleft plate, and proceeds to attach it to the cap of the patient, in order to maintain the whole in the nasal fossæ. The constriction is afterwards augmented gradually by drawing each time with greater force upon the knot-tightener, and in the space of a few days the section of the polypus is completed.

V. *Another process of Desault*, less embarrassing than the preceding, is that which consists in introducing the noose of a long thread into the pharynx through the nostril by means of a gum elastic sound or bougie. The operator proceeds to seize hold of this noose with the finger as soon as it appears above the velum palati; brings it to the exterior through the mouth; detaches from it the guiding sound, which he withdraws through the nose; fixes to it an ordinary thread intended for the same uses as in the process of Brasdor; makes it ascend into the posterior fauces in supporting it with two fingers, while an aid draws its two extremities, which have remained free, to the anterior opening of the nose; after which they are introduced into the knot-tightener in the manner described above. If the fingers were not sufficiently long to follow the noose of the ligature as far as the posterior opening of the nares, two threads in place of one attached to this ligature, at an interval of an inch apart, and each of them afterwards passed into a canula could be advantageously substituted.

VI.—This process was still further modified by Desault himself, with the view especially of more readily applying it to polypi of the pharynx. After having brought from the mouth and throat outside of the nasal fossæ, the extremity of one ligature, and the two ends of a noose of thread of a different color, he introduced into his *canula*,

which is slightly curved, the extremity of the ligature which was left in the mouth; penetrated with this canula to the bottom of the pharynx; made use of it to pass the thread around the polypus; then caused to be passed upon it the noose of the accessory thread, which an assistant is afterwards directed to draw through the nostril, and whose object is to bring through this passage, after the manner of a hook, the second head of the ligature, which is immediately introduced as well as the first, through the ordinary knot-tightener.

VII.—*Boyer*, who approves of these different methods, and has made trial of the greater part of them with success, has nevertheless found it advantageous, under many circumstances, to substitute a catgut, to the cord of thread recommended by Desault.

VIII.—*A. Dubois*, (*P. Dubois*, *Thèse*, Paris, 1821,) with a view of preventing the noose of the ligature from becoming effaced before having arrived upon the root of the polypus, recommended to hold it enclosed up to that point in a piece of elastic sound, of about three inches long, which was afterwards drawn to the outside through the nose by means of tractions so applied, as if we intended to turn this ligature upon a pulley, while acting temporarily upon one of its extremities only. The sound having been removed, we draw upon the other end of the ligature, in order to bring them out upon the same line, and insert both into a knot-tightener. Unfortunately this piece of the sound does not always follow the direction we would wish to give to it. It slips and escapes, sometimes to one side, sometimes to the other, and frequently does more harm than good; so that contrivances still continue to be devised for holding the ligature open in a proper manner until it reaches to the top of the pharynx.

IX. *Process of M. Rigaud*.—In the month of January, 1829, two new instruments were proposed for this purpose. One which its inventor, *M. Rigaud*, calls a *polypodome* is composed of three stems of steel susceptible of being moved, advanced, and withdrawn separately or together in a strong canula. Being curved into an arc at their extremity, they form a kind of forceps, with three branches, which are opened or shut at pleasure. Each one has a bird's-eye at its extremity; the middle portion of the ligature is passed into these openings, and its extremities are immediately brought through the nose by means of *Bellocq's* sound. The forceps with its three branches approximated, are then conducted into the posterior fauces. In that part they are separated to a greater or less degree, according as it becomes requisite to give to the noose more or less considerable extent. Afterwards their summit is elevated in the same manner as if we were using the polypus forceps. In order to disengage the thread, it suffices to draw with a certain degree of force upon the extremities which hang out of the nose. The two halves of their terminal cleft, being sufficiently elastic to retain the noose, which is in no way drawn upon, allow it to escape immediately upon the pedicle of the tumor. The rest of the process has nothing particular.

X. The other, which is that of *M. Felix Hatin*, (*Mém. sur de Nouv. Instrum., &c., et supp.*, 1830,) is a plate of polished metal curved near its pharyngeal extremity; being dilated and rounded upon its

convex surface, it may serve two purposes or fulfil two indications. In fact, its horizontal portion depresses the tongue exceedingly well, while the other obliges the ligature to glide upon it until it meets the polypus. It is an instrument of very simple construction, which its inventor uses with success, and which I myself have made trial of in two instances; but which could, if necessary, be replaced by a tea-spoon bent forwards towards the root of its handle. The polypodome of M. Rigaud occupies less space, conceals the parts less, and is better calculated to conduct the ligature where, and as we wish, and could in fact conduct it advantageously without passing through the mouth, upon certain polypi in the anterior portion of the nasal fossæ, but it has but little solidity, and is more inconvenient than I had at first considered it.

XI. *The knot-tightener* itself has attracted the attention of a great number of practitioners. Bichat recommends that it should be jointed (*brisé*) in order that we may, if necessary, give it a greater or less degree of length, without displacing it. That of M. Graefe, which is composed of two pieces, one of which is made to slide upon the other, enables us to strangulate the polypus with force, without disturbing the extremity of the threads. But the most ingenious of all is the one which Roderick succeeded in constructing to cure himself of a polypus which had resisted all the efforts of the surgeons of Brussels. (See *Ligature en masse*.) The chaplet, which it makes, perfectly accommodates itself to the curvatures of the nasal fossæ, and fatigues them incomparably less by its presence than any other. Its balls may be made of wood, bone, or metal, and M. Sauter constructs them out of the point of the horn of ruminating animals. M. Mayor recommends that they should be made of silver, tin, &c.; finally, in place of a winch, M. Bouchet makes use of a small barrel, while M. Levancier (*Arch. Gén. de Med.*, t. II., p. 467,) confines himself to a simple clapper (*cliquet*.) M. Braun has also deemed it necessary to modify this instrument, which had already been suggested by Girault or Riolan.

XII. *Appreciation*.—The *process* described by *Dionis*, and which is intended for the adjustment upon the pedicle of the tumor by means of a crow-beaked forceps of a running knot, one of the extremities of which is afterwards made to pass through the nostril by means of a long needle of lead or brass, in order to bring it out through the mouth, while the other remains at the extremity of the nose, is scarcely ever applicable. That of Glandorp, as modified by Gorter, afterwards revived by Heister, who, in order to adjust his ligature, successfully employed, on a woman 70 years of age, a curved needle mounted upon a handle, pierced with an eye near its point, and which is quite similar in every respect, moreover, to the needle invented by Goulard, in order to tie the intercostal artery, cannot however be reasonably made trial of except in those cases where the polypus has approached very near the opening of the nose. As the anterior nasal opening descends below the palatine wall of the nares, the ligature necessarily acts with force against the facial border of this wall, when we draw upon it through the nose, and tends constantly to cut into it, or at least to excoriate it. It was to remedy this defect that Levret proposed to add a sleeve to the two ends of the seton, which

he sometimes recommended to be used. It was for the same object that M. Félix Hatin recommended a small plate, which was to be kept vertically behind the lobule of the nose, where it was to fulfil the office of a pulley, but which plate could be perfectly well replaced by a steel stem pierced with an eye for the passage of the thread. Finally, the ligature is not adapted to polypi with a large base, nor to those that are vesicular. In whatever manner it may have been applied, it is necessary to tighten it daily up to the time of the separation of the body which it embraces. It is no longer applied at the present time as formerly, with the simple object of rendering the excision or tearing out of the polypus more easy or less dangerous, or with the intention of protecting us against hemorrhage. But it is with the professed intention of producing mortification of the polypus by intercepting the passage of the fluids through its pedicle, which result moreover it effects by ultimately cutting completely through it. Consequently we should be prepared to find that the tumor has become engorged immediately after the operation, then shrunk or decomposed, and requiring the employment of the forceps or some kind of hook when its root has been divided. - On the other hand, injections of vinegar and water, alum water, or any styptic or antiseptic solution whatever, are in such cases auxiliaries not to be neglected. Prudence also suggests that the patient should be constantly kept with his head inclined forward, in order that the putrid matters may not descend into the digestive passages. Should the polypus moreover be about to fall into the pharynx, it would be important to introduce into it beforehand a thread by means of a needle. Otherwise, it might pass towards the opening of the larynx in becoming detached, and give rise to the apprehension of suffocation. After this separation, it is well to continue still for the space of a week or two the detergent, astringent, or styptic injections, so long in fact as the nostril shall not have entirely ceased to suppurate. Having pointed out while speaking of these different methods, the merits of each one of them in particular, it would be deemed, I presume, altogether unnecessary to compare them here in their ensemble in order to appreciate their relative value. As there is no one of them which can claim the preference in an absolute manner, it must be to the judgment of the surgeon that the choice is to be left, of the process which is best adapted for employment in each case considered separately.

XIII. *Polypi of the Velum Palati.*—It may happen that vegetations, small polypi and pediculated tumors, will develop themselves upon the nasal surface of the free border of the velum palati. This is a disease of which I have seen three instances. There would be no objection to treating it by the ligature or arrachement; but excision would be evidently better adapted to it. Securing the tumor with one hand by means of an erigne or claw forceps, the surgeon excises it with the other with a strong pair of scissors or straight bistoury. The two patients whom I operated upon in this manner found themselves cured on the following day.

[*Calculi in the Nasal Fossæ.*—*Case of an Osseo-calculous or Bony circular Plate in the Diaphragm.*—We avail ourselves here, chiefly of a very learned and complete paper on *calculi in the nasal*

*fossæ*, by M. Demarquay, in the Archives Générales of Paris (4e ser., t. VIII., Juin, 1845, p. 174 et seq.) Though this subject has been long neglected; cases of this description of calculi have been noticed by J. M. de Gardi, (*Pratica*, Venise, 1502, post 2, cap. 14, p. 308,) Thos. Bartholin, (*Histor. Anat. Rara*, centur. 1, hist. 13, p. 47, 1654, et *Histor.* cent. 4, p. 404, historia 85,) Clauder, (*Ephemer. Curios.*, dec. 2, an. 13, obs. 78, an. 1685,) Kern, (*Observ.*, 46, dec. 3, an. 5 and 6; *Ephem. Cur. Nat.*, p. 100, an. 1700,) Vitus Reidlinus, (*Ephem.*, dec. 3, an. 9 and 10, obs. 145, p. 268, an. 1706,) Wepfer, (*Observ.*, 192, p. 905, an. 1727,) Ruysch, (*Obs. Anat.*, Amsterdam, obs. 44, p. 42, an. 1733,) Plater, (*De Olfactus Lesione*, lib. 1, cap. 9, p. 264, an. 1736,) Horn, (in Smuker, obs. 22, p. 289, an. 1788,) M. Saviales, (*Bull. de la Fac. de Méd.*, t. IV., p. 44, an. 1814,) M. Graefe, (*Annales d'Oculistique*, t. VIII., 4th and 5th liv., p. 203,) Thouret, (*Arch. Gén. de Méd.*, t. XIX., p. 27, an. 1829,) M. Brodie (*Ann. de Therap., Méd. et Chir.*, No. 2, May, 1844,) and M. Blandin.

M. Graefe has properly given them the name of *rhinolites*, and the earthy and saline materials of which they are composed are readily explicable by the elementary composition of the secretions from which they are derived, viz: chiefly from those of the Schneiderian membrane, lachrymal apparatus, &c. There is no doubt, however, in our minds that earthy and saline calculous concretions may be formed in any of the cavities, passages and surfaces of the entire organism, and also in the substance of any of the tissues. Thus, at the Seamen's Retreat Hospital, New York, while the writer of this was at the head of that institution, a robust, tall, corpulent old sailor, aged 70, every way of good constitution and well formed and erect, and laboring under no other disease but an extensive sore on the leg, caused by intemperate habits, and of the character of those so familiarly known as "rum-legs," in a fit of despondency threw himself from the piazza of the hospital, eighty feet, which caused his immediate death. In examining the dead body, in which we found every rib on one side fractured and extravasation into the pleura, ventricles and base of the brain, &c.; we found also, on inspecting the diaphragm, a large regularly formed flat *osseous or earthy plate*, which was *completely circular*, and about two inches in diameter and a quarter of an inch thick in every part of it, flat on both sides, and *perfectly imbedded*, or as it were sewn into the middle of the muscular fibres of the diaphragm, its two planes corresponding precisely to, and being accurately covered by, those of this partition.

It is to be remarked, as suggested by M. Graefe, that where an arthritic or lithic diathesis exists, earthy deposits and calculous concretions may be expected to be found more extensively and in every part of the body.

M. Demarquay, after his investigations, comes to these conclusions: 1. *Rhinolites* may be found alone or in considerable number in the nasal fossæ, and especially in the lower part and lower meatus of these fossæ; 2. In the frontal sinus, and from thence descend into the fossæ, or into the sinus maxillare, or they may be developed in the antrum of Highmore, as mentioned by Lanzoni (*Ephem. Cur. Nat.*, deca. 3, an. 9 and 10, obs. 143, p. 267); 3. They may shut up the nares and incline the septum to one or the other side, or destroy it in

part; 4. That they vary from the size of a bean to that of a pigeon's egg; 5. That they may be isolated, as is usually the case, or enveloped in a shell; 6. That they are of a blackish, greyish, or whitish color, and have asperities or a chagreen aspect on their surface; and 7. That they may be homogeneous or may be formed on a nucleus, as on the kernel of fruit, the root of an incisor tooth, &c.

Exposed as the nares constantly are to the introduction of foreign bodies, and the more so in inspiration, it is easily conceived that calculi might be formed *entirely* by aggregation of particles of dust or fine pulverized earth inhaled from without, without any distinct nucleus, and thus by admixture with the solid depositions from the secretions of the nares, sinuses, &c., give rise to the supposition of an organic process from within the system. This idea does not appear to have occurred to M. Demarquay.

The analysis of these calculi, as given by Axman, Prout and M. Bouchardat, is:

|                                                               |       |
|---------------------------------------------------------------|-------|
| Animal matter (albumen, mucilage, fibrine, fat and osmazome), | 0.35  |
| Phosphate of lime, - - - - -                                  | 0.8   |
| Carbonate " - - - - -                                         | 0.225 |
| Carbonate of magnesia, - - - - -                              | 0.125 |

Traces of soda, muriate and carbonate of soda, and oxyde of iron.  
Mucus.

Phosphate of magnesia.

Thus they constitute, as M. Demarquay says, an exaggeration or excess of the normal secretions of the parts. Differing from M. Graefe, he imputes their formation not so much to an arthritic diathesis as to a chronic inflammation of the nasal fossa and lachrymal gland, causing a vitiated or altered state of the secretions of those organs. Also an abnormally contracted condition of the passages may have an influence, by the obstruction it would create to the free escape of the secretions. Among the symptoms to be noted are, a sensation of dryness and weight in the passages, obtuse and sometimes acute pain, occasionally periodical cephalalgia, &c., and finally inflammation of the parts encroached upon, erosion, caries, fœtid purulent discharges, &c.

They may be sometimes diagnosed by a *metallic* sound imparted to the exploring instrument. The treatment, when their volume requires the aid of surgery, is the same as that for the extraction of polypi, together with a more careful attention to detergent injections and general remedies to change the morbid action.

*Successful removal of Polypi from the Frontal Sinus.*—One of the most extraordinary surgical cases on record, and one also of the most extraordinary instances of the triumph of surgical art, is that of a boy aged ten years, operated upon by Dr. C. C. Wuth, (*British and Foreign Med. Review*, January, 1846, p. 186,) for a remarkable enlargement of the left frontal sinus, with frightful protrusion and disorganization of the entire left eye; both of which had existed nine years, and caused constant severe pain in the head, loss of rest, emaciation, &c. Many practitioners had been consulted and various remedies used, but no one it appears had ever suspected the true diagnosis, until Dr. Wuth suggested that the whole tumor and deformity arose from polypi within the frontal sinus. It is proper to

state that the socket of one orbit had become so much displaced forward by the internal pressure, that the left eye was almost entirely extruded from it, presenting a most hideous aspect. The globe in fact lay on a level with the back of the nose, and projected laterally over the cheek bone on the left side, while downward it reached to the point of the nose. The lids for three years had ceased to cover it, and the protrusion of the ball was the greater from the orbicularis acting now as a powerful sphincter, excited into this forcible antagonism, Dr. Wuth thinks, in order to resist the pressure of the tumor from within. The cornea was partially ulcerated, the vessels of the conjunctiva varicose, and a constant flow of tears came from the parts. The regions of the frontal and nasal bones were greatly protruded, and the left side and the back of the nose formed a flat surface by reason of the pressure, so that the nostril on that side was nearly closed. The skin was thickened and doughy to the touch, and the left eyebrow deviated upwards at a great distance from the right, and had at its outer and under part a small opening, from whence there constantly oozed out a whitish mucous fluid. An attack of measles is supposed to have been the cause of this terrible mischief.

Dr. Wuth proceeded to operate as follows: first by a vertical incision two inches long, from the root of the nose upwards through the soft parts, and a horizontal one from this of the same length, close above the eyebrow. Dissecting off the triangular flap thus circumscribed, he next proceeded to trephine the frontal sinus, remarking in the middle of the superciliary arch a small hole in the bone, which accounted for the mucous discharge already mentioned, [and but for which salutary drain probably death would have long before ensued. T.] This oozing however had caused, in the soft parts of the neighborhood, a considerable degree of inflammation and a fungoid condition of the tissues, which gave rise to some hemorrhage. On trephining into the frontal sinus by two openings, an *immense quantity of polypi protruded, being connected together like grapes, and covered with a milk-white fluid.* The greater part of these were removed by the scissors. Internally they were yellow and semi-transparent, and each had two or three vessels in them, radiating off branches in all directions. In the upper portion of the sinus the polypi were of a mucous or cellular texture, and softer to the feel, but firm. Out of these could be made too ooze, by pressure, a white slimy fluid. In the middle of the abnormally dilated sinus the morbid product was denser and more opaque; and posteriorly and towards the parietes it was of a fibrous structure. The cavity terminated towards its inner and outer sides in small sinuses or cellular spaces, in which the polypi lay firmly imbedded. As the surgeon found the osseous partition which separated the sinus from the brain, so thin in fact that it yielded to pressure and imparted to the finger the pulsations (the diastole and systole) of the encephalon, great caution was required in detaching the morbid growths from it, or in the application afterwards of such cauterizing means as would not cause too much irritation. He now bored through the osseous parts from the cavity of the nose to the frontal sinus, as the ethmoid cells, conchæ, &c., and introduced a silver canula, so that the fluid collected in the sinus might flow off unconfined; and also to remedy the flow of tears over the

ball, perforated the nasal bone from without inwards, so as to meet the artificial canal previously made, and inserted in this second also a silver tube. This last was removed and closed when the tears had reacquired their natural passage. The first canula into the sinus was also afterwards removed, and the parts firmly cicatrized in the space of twelve months; by which time the globe and the bones had almost resumed their natural dimensions and position; the ulcer of the cornea also having healed and left only a leucoma, but the sight much improved. From the first night the patient enjoyed such sleep as he had not had for years. The first *six weeks* he spent chiefly in sleeping and eating, which soon repaired his exhausted constitution. The cure in fact has continued complete and perfect, now embracing a period of some years. To overcome the adhesions of the polypi, and to restrain new growths on the parietes of the sinus, Dr. Wuth properly declined the use of the nitrate of silver and employed laudanum, Goulard's extract and creosote, pencilling the parietes with a mixture of equal parts of the two former, and then applying a salve composed of an ounce of zinc ointment and ten drops of creosote spread on lint.

Dr. Wuth, from the above highly instructive case, the successful operation for which does him so much honor, deduces very naturally the following conclusions: 1. The power of vision to continue under general traction and elongation of the optic nerve. 2. The frontal sinus may be enlarged to an enormous extent, which, in this case, was equal to the *volume of three hen's eggs!* 3. The return of this osseous cavity almost to its normal form. 4. The complete division of the supra-orbital and frontal nerves without injuring vision. 5. Pain is not a pathognomonic sign of the malignant or benignant nature of a swelling—a fact illustrated also by cases of induration of the mammæ and other organs, which, by their spontaneous disappearance, show their non-malignant nature.

There is a case of a *gentleman now living in New York*, aged about 55, who has been frequently seen by Dr. Mott, myself and others, and in whom, in fact, there has existed for many years such a frightful protrusion of the socket and balls of both eyes, and the whole of the lower portion of the frontal bones and outer angles of the orbits, as to have excited remark among all who have ever witnessed this melancholy deformity. The sight of both eyes is now entirely lost, as both are amaurotic, though both balls can yet be covered by the lids, not however without difficulty. The organization of the substance of the tunics of the globes is not materially altered, though they both, and especially one, stand out on a level with the cheek. Is it not probable that this case is one of polypi in the frontal sinuses? Some fifteen years ago it was seriously stated, that one day, in a violent fit of sneezing, one globe actually came out of its shallow socket, and hung upon his cheek by its optic nerve until replaced by a physician who happened to be present! This does not now seem in the least marvellous, after reading the case of Dr. Wuth, above. T.]

## ARTICLE II.—SINUS MAXILLARE.

§ I.—*Perforation.*

The maxillary sinus is frequently the seat of diseases, to relieve which perforation has repeatedly been resorted to. *The worms*, which Bordenave, Fortassin, Heysham, &c., state to have encountered here, would unquestionably exact this operation if it were possible to recognize the existence of these animals during the life of the patient. The same remarks apply to *peletons of adipocire*, which, as it has been stated, sometimes form in this part, also to *balls* which, as Ravaton (*Chir. d'Armée*, p. 114) and M. Petit (*Journ. Hebdom.*, t. II., p. 47) have seen, may get caught here and remain even as long as 25 years; but it is especially with the view of removing *abscesses*, *hydropsy*, ulcerations, and *fungus, fibrous*, and carcinomatous tumors, also polypi, necrosis, and caries of the cavity, that this operation is had recourse to.

A. Jourdain, who about the middle of the last century so strenuously insisted upon the utility of medicated *injections* through the natural opening of the sinus, and upon the inutility of its perforation in almost all its diseases, has not succeeded, notwithstanding the numerous arguments which he advances, in convincing practitioners, and his doctrine at the present day is advocated by no one. On one hand it has been found most frequently, whatever may have been said on this subject, that it is extremely difficult to discover, at the middle of the median meatus of the nasal fossæ, the entrance of the sinus by means of a sound; and on the other hand that this opening, which is more frequently obliterated in consequence of disease than in any other manner, would afford no assistance even though it should be re-established, and that taking all things into consideration, the artificial perforation, which is less difficult and more certain, ought to have the preference.

B. *Perforation of the Alveoli.*—Of the different methods of effecting the opening into the sinus maxillare, the most ancient is not, as is generally believed, that which consists in penetrating through the alveoli of the molar teeth. Molinetti, who wrote in 1675, says, that in a patient who was tormented with agonizing pains, a crucial incision was made into the cheek, and that by means of the crown of a trephine they penetrated into the antrum highmorianum, which was the seat of an abscess. It is also an error to attribute the honor of this operation to *Meibomius*. Zwingler had, after the extraction of several necrosed and loose teeth, cured a caries of the maxillary bone, by dilating the diseased alveolus with prepared sponge. Ruysch makes the remark that Vanuessen could not succeed in curing a polypus until after having extracted several molar teeth and cauterized their alveoli with a red hot iron, so as to be enabled to pass the finger into the maxillary sinus. Some years subsequently, W. Cowper, in 1697, according to Drake, who has formally recommended it, perforated the alveolus of the first molar and penetrated into the sinus with a kind of stilette, in order to be enabled to inject liquids into it. Moreover Meibomius, whose researches were published in 1718, is so far from having invented this method, that he limited himself

to the extraction of a tooth, in order to give issue to the matters accumulated in the sinus, with the perforation of which he appears to be wholly unacquainted. It was also the practice that Saint-Yves followed with success, in a patient who for a long time had had a fistula, accompanied with destruction of the floor of the orbit; so that it was not until Cheselden had revived this operation that the attention of practitioners was directed towards it. This surgeon recommends that we should rather extract the third or the fourth than the first or the second molar teeth, as indicated by Juncker, and that if there exists an osseous fistula we should content ourselves with enlarging it in place of piercing through the bottom of the alveoli. Since that epoch the perforation of the alveoli has been modified by different authors. Heuermann, who also prefers the alveolus of one of the last teeth, recommends, if the pus does not immediately escape, to perforate the sinus with a probe, and to place in the opening a canula, in order to prevent its too speedy obliteration. Bordenave judiciously remarks, that, with the exception of the first, all the molar teeth correspond to the sinus, and that consequently if there is one of them carious or more painful than the others, it is this which should be removed by preference, but that it is advisable to extract the third if they are all equally sound. On the other hand he recommends that we should extract all those which are altered, provided that they can no longer be of any service. A canula of lead appears to him to be more suitable for keeping, during a certain space of time, the aperture open, than the sound and bougies, and he does not think, moreover, that the process should be the same in all cases. Desault, who adopted the recommendation of Bordenave, commenced the operation with a perforating trephine, mounted upon a many-sided handle, and terminated it with another instrument of the same kind, but the point of which was blunt, in order not to wound the opposite wall of the sinus. According to B. Bell, if we have our choice we ought to extract one of the posterior teeth, and in the interval between the dressing keep the opening shut by means of a stopper of wood. Richter perforated the alveolus with a trochar: he cautions us against leaving the canula which is placed there open, because portions of the food might get into it and be introduced into the sinus. Deschamps recommends that we should leave this canula permanently in, fastening it by means of a thread round one of the teeth. In conclusion, the method called that of Meibomius, which possesses the advantage of placing the opening at the most depending point of the sinus, of leaving no visible cicatrix at the exterior, the execution of which, moreover, is as simple as it is easy, and preferable to every other when there exists a carious tooth, ought, in my opinion, to be rejected under contrary circumstances, and where the alveoli have for a long time been divested of their small bones, and become entirely obliterated.

*C. Method of Lamorier.*—Lamorier recommends in such cases that we should penetrate into the sinus maxillare, immediately below the zygomatic process, between the cheek bone and the third molar tooth. This is the point which corresponds to the summit of the cavity, where the walls of the sinus present the least degree of thickness, and where it may be reached with most facility. An as-

sistant, provided with a blunt hook, draws the labial angle outwards and upwards. The operator incises the fibro-mucous membrane which covers the bone, at the point designated, by means of a scalpel or good bistoury; then perforates the osseous wall with a solid pointed instrument; enlarges the opening as much as he judges necessary, and finishes by introducing into it a tent of lint.

*D. Method of Molinetti.*—Other surgeons, going back to the operation of Molinetti, have recommended that we should first divide the cheek between the projection of the malar bone and the suborbital foramen, then to penetrate through this wound into the interior of the sinus; but unless we are forced to do so by circumstances, we should avoid this division of the external soft parts.

*E. Method of Runge.*—In place of perforators, one sharp-pointed and triangular, the other blunt, invented by Desault for this kind of operation, Runge, who had performed it in the year 1740, made use simply of a strong scalpel, which, in order to enlarge his first puncture, he took care to turn four or five times upon its axis. The trephine which C. Bell uses for the same purpose, has neither more nor fewer inconveniences than the scalpel of Runge or the perforating trephine of Desault.

*F. Method of Gooch.*—In a patient who had no longer any molar teeth, the idea occurred to Gooch of perforating the antrum high-morianum on its nasal wall, and of inserting therein a leaden canula. Ol. Acrel had already made use of a process very analogous: that is to say, that after having operated in the manner of Cowper, he inserted through the nose another canula into the sinus, which had a fistulous opening upon that part of it.

*G. Method of Ruffel.*—A buccal fistula of the sinus maxillare suggested to Ruffel the idea of penetrating that cavity with a trochar, and of compelling it to come out above the gum, in order thereby to establish a counter opening. A seton was then introduced and kept in this passage during the space of six weeks, with such benefit that success crowned the enterprise of the surgeon.

*H. Method of Callisen.*—Callisen, who adopts the seton of Ruffel, and imitated in this by Zang, thinks with reason that if the fluctuation should become perceptible at the vault of the palate that the artificial opening should be established there. Busch and Henkel have perfectly succeeded by means of a meche introduced through a fistula in the floor of the orbit, and brought into the mouth through an opening in the alveoli. Bertrandi proceeded in the same manner, with the exception of not using the seton, in a patient who could not open his mouth and who also had a fistula in the orbital wall of the sinus.

*I. Method of Weinhold.*—In the process which is attributed to Weinhold, the surgeon first directs his instrument to the upper and outer part of the canine fossa, directs it obliquely downwards and outwards, carefully avoids the branches of the suborbital nerve, perforates the sinus and then places a roll of lint in the wound. If the sinus has no other issue, Weinhold recommends that we should perforate it through and through, either by pushing the first instrument through the palatine vault into the mouth, or by means of a curved needle above the alveoli, when we wish to place the counter opening external to the gum. An eye which both instruments

have, enables us at the same time to pass through the sinus, the conducting thread of a meche of lint destined to perform the duty of a seton, and which is besmeared with any ointment that may be suitable.

J. This is a method, as we perceive, which is quite similar to that of Ruffel or Henkel, and which may be made trial of as well as that of Desault or Lamorier. It is also analogous to that of *Nessi*, who, after having freely laid open the sinus through the mouth, perforates it with a trochar and proceeds to destroy also its anterior wall to a considerable extent below the cheek bone, or in the canine fossæ.

K. *Appreciation*.—In conclusion, the perforation of the maxillary sinus is performed at the point of election or at that of necessity. The first may vary according to the taste or ideas of the operator. The other, on the contrary, is determined by circumstances. In cases of abscess, hydropsy, fistulas, and ulcerations, we almost always operate at the point of election. In such cases, however slightly one of the molar teeth may be diseased, it is to be extracted as well as the neighboring tooth; we then divide the gum down to the bone; outwardly, inwardly, posteriorly. and in front, as if for the purpose of forming thereby a square-shaped flap, and then isolate it entirely from the surrounding tissues; after which the alveoli are to be perforated by means of the instruments of Desault, and an opening made sufficiently large to enable us to penetrate with the finger into the sinus. Boyer, who follows this process, insists with reason upon the necessity of never making the dimensions of the opening too small. Should all the teeth be perfectly sound, or should the patient have lost them for a long time, and the alveolar border, rounded off and smooth, should have preserved all its solidity, the method of Desault or Lamorier would deserve the preference. Upon the supposition that this would not succeed, there would be plenty of time to adopt that of Meibomius, which it cannot be denied is incomparably more painful and more formidable to the patient.

L. *The Author*.—If, as happens frequently, and an example of which has been published by M. Sauv  , (*Bull. de la Fac. de M  d.*, t. V., p. 9,) the sinus is distended by any liquid, its anterior wall, swollen out in the form of a border under the cheek, is in general so soft that a bistoury or scalpel perforates it without any difficulty. The operation is then extremely simple. Having freely incised the superior part of this border transversely between the cheek and the malar bone, I excise its inferior portion with a second cut of the bistoury. The loss of substance thus made remains fistulous, and prevents the sinus from filling up a second time. The three patients whom I treated in this manner were promptly cured.

##   II.—*Foreign Bodies.—Polypi.*

It is also through the anterior wall of the sinus that we must penetrate if we have to extract only a foreign body, as for example, a ball, or shot, or some splinters of bone. When, on the contrary, we wish to remove a polypus, fungus or necrosis, prudence suggests that we should attack it at the point towards which it appears to have naturally inclined, or which it has most seriously altered. Du-

bertrand found that he could succeed in this manner in extirpating a polypus of this kind, by uniting two alveoli by breaking through their septum, and then removing the fragments of carious bones; while Caumont was obliged, in a patient who had undergone a similar operation without benefit, to attack the tumor where it showed itself at the canine fossa, and Chastenot on the other hand, found it necessary in the case cited by him, to destroy almost the half of the maxillary bone with its palatine process, in order to effect the same object. However this may be, when the antrum highmorianum is opened with the sole view of giving a ready egress to the matters which it secretes or exhales, the requirements of the operation are reduced to simple detergent, astringent, antiseptic or dessicative injections, until the bottom of the wound is covered with cellular granulations. Should there exist at the same time necrosed osseous fragments, these are to be destroyed. In such cases it frequently becomes advantageous to prolong the incisions, to enlarge the openings, and to have recourse to the chisel, the saw, cutting pliers, gouge and mallet. The same thing takes place in cases of exostosis, and every other alteration of the osseous tissue. When the sinus encloses a polypus, the tumor is to be treated in the same manner as if it were in the nose, with this difference, that the tearing of it out, which is almost always applicable, rarely fails to effect our object, and that we cannot perceive at least what advantage would in this case be presented by the ligature, which was still employed by Sylvi, (*Soc. de Santé de Lyon*, p. 121, 1798,) for a polypus, which projected at the same time into the mouth, and into the zygomatic and temporal fossæ.

After having isolated and denuded its periphery, and laid bare its pedicle or base, it is then to be secured by a polypus forceps, or if we should find it more convenient, by the forceps of Museux, frequently used by Dupuytren. We then tear it out by drawing it towards us, or what is as well, by twisting it upon itself. Should it not possess sufficient firmness to resist the action of the forceps, we remove it by excision after having forced it to yield as much as possible; and if any bridles or osseous lamellæ should interfere with its extraction, they should be divided without hesitation, unless, however, there should be some danger in meddling with them. When it has more breadth than prominence, when instead of a polypus we find fungosities or any other degenerescence, we are sometimes obliged to remove them layer by layer; either by means of the ordinary or blunt-pointed bistoury, by the scalpel with a truncated, short and broad point, somewhat curved on its flat side, like the knife of F. de Hilden, or that devised by Pelletan and eulogized by Boyer, or finally by means of any other appropriate instrument, as for example, by a kind of cutting scoop, like that of Bartisch. On the other hand, should the tumor be of too large a size to be readily extracted at the maxillo-labial groove, it would be necessary to lay open the lip freely throughout its whole height, or one of its commissures in the direction which was most suitable. The twisted suture in a wound of this kind renders agglutination so easy a matter, that we should be really culpable in neglecting it whenever it should appear that the operation would be thereby simplified. Sylvi, by cut-

ting into the temporal fossa, in order to extract and cauterize a remaining branch of a polypus in the sinus, lost his patient at the expiration of three weeks ; but Cartier, (*Soc. de Santé de Lyon*, pp. 122, 123,) after a similar operation, had the good fortune to cure his. Caustics may be used to destroy whatever arrachement and excision have not enabled us to remove. The mineral acids, the butter of antimony, and better than all this, the nitrate acid of mercury, introduced by means of a pencil wrapped in rolls of lint, have the advantage of not transmitting their action to a distance like the actual cautery, which at this point in particular is to be especially dreaded, because of the proximity of the eye. It is however important not to be forgotten, that Garengéot could not succeed in curing a fungous mass in the antrum which had resisted repeated excisions, extirpation and chemical escharotics, except by destroying it by means of the red-hot iron. Nitrate of silver, alum, sulphate of iron or copper, and all those substances which are rather styptic than really caustic, are scarcely applicable, in fact, except to vegetations, small ulcers and tumefactions ; in a word, to alterations disconnected with the bones, and which have no malignant character. It is unnecessary to say that, should any deviated tooth be the cause of the disease, it would be necessary to proceed in search of it and to extract it immediately. The triumphs of art contain in this respect facts that are extremely curious ; such, for example, is that which Dubois has published. This practitioner, supposing that he was cutting down on a fungous tumor, saw issue out nothing but a liquid and thin matter from the maxillary sinus, which he had just freely laid open above the dental arcade. The wound soon closed up, but the tumor remained. With the assent of Pelletan, Boyer, &c., Dubois extracted three teeth, removed a large portion of the alveolar border, thus laid open the antrum in its whole extent, and found no fungus, but perceived in the upper part of the cavity, in the substance of its anterior wall, a white point, which was no other than an incisor tooth, the root of which was found to be rivetted as it were into the sinus.

M. Blasius (*Arch. Gén. de Méd.*, 3rd ser., t. II., p. 98,) also succeeded in curing a hydropsy of the sinus maxillare by extracting an abnormal tooth. A tooth of this kind, which had become imbedded in the ascending process, gave rise to the production of an enormous tumor in a patient of M. Gensoul, (*Lett. Chir.*, 1833.) As to hemorrhage, these different manipulations sometimes render it sufficiently copious to oblige us temporarily to suspend the operation. Should it not cease spontaneously, the eau de Ravel, oxycrat or tamponing with small balls of lint sprinkled with colophane. or even if necessary, the iron heated to a white heat, are at the command of the surgeon and will always enable us to apply an efficient remedy. It is also for cancerous and osteous-sarcomatous tumors of the maxillary sinus that exsection and amputation of the upper jaw have been most frequently performed. In addition to the examples which I have elsewhere related, (see *Exsection of the Jaws*, Vol. II.) it is necessary to mention also that of M. Bonjour, (*Arch. Gén. de Méd.*, ser. 2nd, t. IV., p. 476,) that of M. Blandin, (*Ibid.*, t. V., p. 162, 2nd ser.,) that communicated to me by M. Chaumet, that of M. Laugier, that of Le Sage, (*Bull. de la Fac. de Méd.*, t. V., p. 258,) and one which

belongs to myself. In this last, (*Gaz. de Médecins, Prat.* t. I., Nos. 1 and 2,) after having incised the soft parts, as has been mentioned, (see *Exsection of the Jaw*, Vol. II.,) I divided the zygomatic arch, the external orbital angle, the ascending process, then the dental arcade and the nares in the mouth, with a cultellaire saw, and removed the entire maxillary bone together with the cancer.

### § III.—*Osseous Cysts.*

Osseous tumors, tumors filled with a thin serosity, as in grenouillette, or with pus, or of a fibrous, fatty or fungous nature, or composed also of many of these elements at the same time, have been frequently noticed outside of the sinus maxillare, and even in the substance of the bones of the face. I have seen, like Chaussier, exostoses in the lower jaw. M. Diday (*Thèse de Concours*, 1839, p. 32,) mentions one situated in the vault of the palate. M. A. Cooper saw one which caused suffocation by pressing upon the epiglottis. Runge, who was one of the first that spoke of these tumors, states that his father and himself have met with *osseous tumors in both jaws*, and that they frequently derive their origin from the point of the root of a tooth. It is also probable that those alleged lymphatic congestions whose walls were found as *thin as parchment*, and which M. Brodie, (*S. Cooper, Surgical Dictionary*, p. 201, 7th ed.) as well as Kirkland, places in the antrum highmorianum, also belong to the same description of disease. Has not Callisen committed a like error in speaking of those tumors with separate compartments, which, according to him, require the extraction of several teeth? Siebold, who saw an osteo-sarcoma between the laminæ of the sinus, and who exsected it without causing any pain, and cured his patient, has distinguished better than his predecessors the actual location of this disease. In fact Runge, who in other respects describes it sufficiently well, and does not omit to mention that by pressing it with the finger it yields, but immediately reacquires its dimensions with a *bruit*, ranges it among diseases of the sinus. Sprengel also charges him with several times having inserted in his dissertation, through inadvertence without doubt, *lower jaw* for *upper jaw*. In this respect, the learned historiographer was evidently deceived. It is certainly to the lower jaw that Runge has reference when he designs to speak of it. Only he has made use, erroneously and improperly, of the term *sinus*, to designate tumors which are situated external to these cavities. These isolated facts, moreover, had not attracted the attention of any one, and it is to Dupuytren to whom we are indebted for having been the first to give in his clinical lectures exact notions on the disease in question. I have now seen a great number of examples. Though the tumor may be situated outside of the sinuses, since it is more frequently seen in the lower than in the upper jaw, and in the ascending process as well as in the substance of this last, nevertheless almost always has certain relations with a diseased condition of the teeth. M. Diday, (*Thèse de Concours*, 1839, p. 36,) adopting this idea, seems even to think that osteo-serous cysts of the face almost always proceed from a dental follicle, and that the greater part of them are disconnected with the substance of the jaw. Though

they are similar in form and external appearances to carcinomatous or fungous tumors, they differ from them especially in this, that they are readily cured by surgical means. Analogy authorizes us to suppose that the various kinds of treatment extolled for lesions of the maxillary sinus would be equally applicable to them; that by extracting the carious teeth in the neighborhood and opening into them at the inner side of the lips or cheeks when they are so situated as to allow of it, we should effect the cure of a great proportion of them; so that there would be no great mischief from confounding them with polypus or other tumors developed in the antrum highmorianum, as happened to the father of Runge and to Dupuytren himself. But up to the present time at least, I have always found it to suffice, as Dupuytren also did, to incise them freely in the mouth or through the cheek, then to throw up injections, and to insert daily a mechie or tent of lint in the wound, in order to bring about their diminution and resolution.

## CHAPTER V.

### AUDITORY APPARATUS.

#### ARTICLE I.—EXTERNAL EAR.

##### § I.—*Otoraphy.*

Pibrac and those who like him, in the last century, condemned the abuse of sutures, were wrong in proscribing also those of the ear. Though it be true that in wounds of the pavillon of this organ, adhesive plasters, position and a bandage, sometimes suffice for procuring a healthy cicatrization, it is also true that these means are for the most part uncertain, and that the suture is infinitely preferable to them. When it is used, whether in the form of the interrupted or whip suture, or in any other manner, I see no reason why the skin only should be included, and that we should place as many points of suture behind as in front, in order to avoid the cartilage, as the ancients recommended. Leschevin has clearly shown, and M. H. Larrey has since proved, that there is no inconvenience in comprising the whole substance of the pavillon in the nooses of the thread. All wounds, for example, by a cutting instrument, and which divide the external ear through and through, ought to be immediately reunited by the suture. Ancient divisions, after having their borders abraded, should be treated in the same manner, conforming ourselves in other respects to the rules laid down in the article on harelip. (See *Otoplasty*, Vol. I.)

##### § II.—*Tumors of the lobe.*

The lobe of the ear may be the seat of tumors of a large size; those that are pyriform, indolent, homogeneous or somewhat granu-

lated, fibrous or *elephantine*. A woman had one of unequal size on each ear; having removed by a V incision into the sound tissues, that of the right side, which was of the size of a nut, I was enabled to reunite the wound by two points of suture, and to cure the patient in three days. It would appear, moreover, according to M. Campbell, (*Arch. Gén. de Méd.*, 2d ser., t. VI., p. 110,) that this description of tumors, which frequently originate from the helix, is apparently endemic at Nipel.

### § III.—*Deformities of the Meatus Auditorius.*

A. When *atresia* of the passage of the ear is complete, and that its source lies in the temporal bone itself, a double example of which I saw in the dead body of a child four years of age, and a second instance on one side only in another child of from ten to twelve years of age, it is incurable, and yields to no kind of medication. To whatever degree, on the contrary, the *contraction* may have proceeded, even though it scarcely admits of the passage of a needle, as was seen by Lamétrie, or that the coarctation is trifling and occupies only one point of the passage, or has invaded the whole extent of the canal, we should make an attempt to remedy it by dilatation. *Caustics*, which were preferred by some ancient authors, might under these circumstances become dangerous and would rarely effect the object in view. The canulas, sounds or tents of larger and larger size, that are used, should be still continued a long time after the cure, and even sometimes during life; for the wall of the canal retains almost always a great tendency to contract again. In certain cases the walls of this canal, when simply lying in juxtaposition to each other, cannot be effectually separated except by a metallic canula of a diameter corresponding to that of the auditory passage in the normal state. If the deafness depended evidently upon an anomaly in the curvature of the cartilaginous prolongation of the ear, it could be remedied by placing a gold canula permanently in this passage, an example of which is related by Boyer in his practice.

B. More frequently the external ear is shut up by a membrane or a sort of diaphragm. Unless it should be very remote from the pavillon, this membrane should be laid open by a crucial incision with the bistoury. The flaps are afterwards to be excised with the same instrument or a small pair of scissors, while they are successively raised up by means of a hook. Others have recommended that it should be perforated with a trochar, and its destruction completed by the aid of dilating bodies; but this method is not as good as the first. Incision, which Paul of Egina adopts when the accidental diaphragm is deeply situated, as in the preceding case, rejected by F. ab Aquapendente under the pretext that it incurs the risk of penetrating into the internal ear, is not proscribed at the present day, except in cases in which it appears to touch the membrane of the tympanum. In these cases we follow the precepts of J. Fabricius, and have recourse to caustic, and the best without contradiction is the lapis infernalis. Leschevin recommends that it should be inserted in a piece of quill, and applied to the bottom of the passage through a silver canula. Three or four cauterizations, at intervals of two or

three days, are generally sufficient. If, however, the septum should be very thick, it would be better, after the manner of Leschevin, to perforate it at whatever depth it may be situated, by means of a very short trochar, whose stilette passed but a very slight distance beyond the end of the canula.

C. It is by the same treatment that we should attack every kind of atresia, complete or incomplete, which is imputable only to defect of conformation of the soft parts, and which is not purely membranous. As soon as the instrument has passed beyond the obstacle which the sudden removal of the resistance indicates, the trochar alone is to be withdrawn, in order to use its canula for the introduction of a bougie to the bottom of the auditory passage, which is to be renewed daily, gradually increasing its size.

#### § IV.—*Foreign Bodies.*

A. An infinite number of *varieties* of foreign bodies may become introduced in the auditory passage, and an infinite number of means have been proposed for their extraction. Archigenes, in compelling the patient to hop on one foot, and to take sternutatories, had the same intention as Celsus, who recommends us to press his head upon a table and to shake it with force, either by raising him up by the feet or striking his sound ear, or letting suddenly fall again, after having raised it, the body which supports him. Alexander of Tralles has suggested the idea of sucking upon them with a tube; and Mesué, who has revived this, like J. Arculanus, has devised for this purpose another instrument, destined exclusively to pump out liquid matters. The suction pump, the instrument invented by M. Deleau, and which can serve to withdraw the air, serosity, pus, &c., as well as for injections into the ear, are referable to the same principle. Leschevin, who alledges that the air contained in the canal of the external ear is the ordinary cause of the buzzing sound and tingling in the ear, had been anticipated by Reusner, who, in order to remedy this inconvenience, recommended a small silver canula left permanently in the auditory passage.

B. *Hardened wax* is dissolved very well by means of oil of sweet almonds, as is remarked by Avicenna, and better still by means of tepid soap and water, or even in pure water, if we believe in the experiments of Haygarth, who rejects oils as less serviceable. A solution of sea salt, as eulogized by J. E. Trempe, also dissolves it. Consequently, when deafness is produced, as so frequently happens in persons of a certain age, by the accumulation of this material, we cause to be introduced several times a day into the ear one of these liquids, either by means of a syringe, or upon cotton which has been saturated with it, and when it has become softened or detached it is removed by means of a scoop,

Duverney, (*Traité de l'organe de l'Ouïe*, 3d part, p. 156, 157, 1683,) states that he had seen in eight or ten instances the wax so inspissated as to resemble plaster, and filling up exactly the bony and cartilaginous passage of the ear. Distinguished surgeons had communicated to him more than thirty similar examples. This species of deafness, according to him, is the most common and the most easily

cured. A famous surgeon of Mons who obtained so much renown for the cure of deafness, undertook only the treatment of this form of the disease. In a patient who had been affected with deafness for a long time, the cavity of the tympanum had become excessively dilated, and the petrous portion of the temporal bone absorbed. These two singular affections were produced, says M. J. Cloquet, (*La Clinique des Hôpit.*, t. IV., No. XXI., and *Séance Acad. Méd.*, 1829,) by the development or accumulation of a ceruminous matter which had become indurated in the interior of the cavity of the tympanum, and which was thrown off in scales, forming a species of false membranes. In another case noticed by M. Jobert, (*Revue Méd.*, June, 1830, p. 414,) the cerumen which filled up the cavity of the tympanum, had transformed the petrous portion into an osseous dilated cavity, in which there remained no vestige of the conformation belonging to the middle and internal ear. The woman mentioned by Bartholin, (Act. Haffn., t. I., obs. 45, p. 82, and Planque, t. XVIII.,) experienced severe pains, especially in the petrous bone. In cleaning the right ear she extracted from it, together with fetid matters, a quantity of sand, and then experienced no more pain.

C. Should *bugs, earwigs, and other insects*, (Wolckamer, Rayger, Lieutaud, (Savages, *Nosol.*, &c., t. IV., p. 232,) Alteyrac, De la Motte, Drouin, and Acrel, have noticed worms here; M. A. Severin, Drouin, and Planque, caterpillars; Ravaton and Wolckamer earwigs; Binniger and Schenk, the larvæ of flies,) which sometimes get into the bottom of the auditory passage, not become entangled in the cotton and pitch, as had already been recommended by Hippocrates, or in a piece of lint saturated with turpentine, which are introduced, in order that they may become caught in it, we may after the manner of Hameck, endeavor to kill them by pouring into the ear the oil of bitter almonds, or like Rhazes, a decoction of peach-leaves. The decoction of *Sedum palustre*, used by Acrel, would produce the same effect. But it is useless at the present day to combat with Verduc, who thought that the pippin apple possessed the property of drawing them to the outside; or with Leschevin, who boasted of the half of a potato being a special antidote for the earwig. It is nevertheless true that that milk appears to possess the property of attracting an earwig, and that M. H. Berard, as well as Alteyrac, succeeded in effecting the expulsion of worms from the auditory passage, by holding a piece of meat upon the ear. It is to be mentioned also, that whether living or dead, we should endeavor to seize hold of these insects and extract them by means of the forceps.

D. As to *solid foreign bodies*, of a certain volume, and which Paul of Egina has properly ranged into two classes, namely, those which absorb humidity, and may become distended in the parts, and those which are impermeable; (MM. Betbeder, Bégin, and Champion, speak of oat-seeds and barley-ears; Dupuytren, of a piece of pencil; De la Motte, of a pea; Saucerotte, of beads of a rosary; F. de Hilden and MM. Dumoustier, Champion, Faber, and M. Maunoir, of cherry-pits,) they demand all the attention of the surgeon. Acute inflammation, abscesses, caries of the bones, cerebral accidents, and violent pains of the head may be caused by their presence. At the opening of the dead body of a patient who died in this manner,

Sabatier found the os petrosum perforated, the dura mater inflamed, and an abscess, together with a *small ball of paper*, which was the cause of all the difficulty, in the substance of the bone itself. In a young girl who had suffered for a long time paroxysms of convulsions, and all kinds of nervous accidents, F. de Hilden (Bonet, *Corps de Méd.*, t. II., p. 405, obs. 4) effected a complete cure by extracting from the ear a foreign body which had been introduced there seven years before. An analogous observation was published in 1829, and scientific collections are crowded with similar examples.

E. M. Larrey nevertheless remarks that in a soldier whom he treated, the foreign body had remained in its place during ten years without producing any accidents. It is well also not to forget that these different bodies, which may be a bean, a small ball of bread, wood, shot, glass, iron, a small pebble, pin, needle, clot of blood, &c., *sometimes come out of themselves* when the first accidents have passed over, after having produced a suppuration more or less abundant. An important point to be noticed in practice especially is this, that patients frequently, as well as their friends, are determined in persisting that there is a foreign body shut up in the ear when it is completely free. A woman greatly alarmed brought her child five years of age to one of the public cliniques in the capital, in order that she might have removed from his ear a cherry pit which had been there for the space of twenty-four hours. All kinds of attempts were made, and these being uselessly repeated every morning for three days, caused excessive pain, inflammation and fever, until when it became hazardous to do anything more, and the idea suggested itself of ascertaining whether the organs of the little patient actually contained the pit sought for, it was perceived that there was nothing there. Such mistakes have frequently given rise to the most serious accidents. Boyer relates two instances; I have met with three or four, and there are few physicians who have not had occasion to witness the same.

F. If by *inclining the ear downwards* we cannot extract these solid foreign bodies, we must endeavor to reach them by means of the forceps when their form is elongated or flattened. A small hook is sometimes the best instrument that can be used for removing those which have a certain degree of softness. It is for these last also that it is advised to divide them and reduce them into fragments by means of a narrow and elongated myrtle-leaf probe, in order afterwards to withdraw them by piecemeal.

G. *Fragile bodies* exact much more precaution. A false pearl, says Boyer, which had become broken in the auditory passage, by a surgeon who was endeavoring to extract it, put the life of the patient in danger, and caused a suppuration of the tympanum and the loss of hearing. We must therefore undertake their search by means of a delicate scoop, which however is to be of sufficient solidity, by following the lower wall of the canal in order to introduce it below the body which is to be removed, and afterwards making use of it as a lever of the first kind, by depressing its handle at the moment of making the extraction. The scoop modified by M. Leroy, which is terminated by an articulated beak which is to be introduced straight, and which is to be elevated by the turn of a screw when it has

passed beyond the foreign body, almost always succeeds in such cases. A noose of lateen or brass wire, or a hair pin, much esteemed by M. Champion, if introduced and brought out in the same manner, would be equally efficacious.

H. A *cherry pit* which had resisted all such manœuvres, finally germinated in the ear to such extent, if M. Donatus is to be believed, (*De Méd. Hist. Mirab.*, lib. II., cap. 22, fol. 77,) that it then became practicable to extract it by drawing upon its twig; but there is no necessity of pointing out the improbability of a statement of this kind. Verduc (*Opérat. &c.*, p. 224, 1721,) however, also states that a pea had germinated in the auditory passage, and M. Dumoustier (*Reflex. sur les Corps Etrang.*, Strasbourg, 1810, p. 5,) makes the same remark of an oat seed as Donatus does of his cherry pit. In such cases the only resources applicable would be to oppose the symptoms with energy or to prevent them, to as great a degree as it was in the power of art to do, and then to await the suppuration.

I. *The process of F. de Hilden*, as adopted by C. de Solingen, and which has been properly rejected, consists in introducing a first canula down to the foreign body, then through this last a second canula, intended to secure this body by means of the teeth which are placed upon its extremity, while a kind of screw-ring or gimlet is inserted to extract the whole at the same time. That which the scoop could not do would not be more advantageously effected by this apparatus, which is much better calculated to force the foreign body into the cavity of the tympanum than to bring it to the exterior. The eyed ear-picker of F. de Hilden, Ravaton's hook, Brambilla's scissors, Leschevin's hook, the flattened probe of Andrieux, and the curved forceps of Dupuytren are not as valuable as the forked pin of M. Champion, and the articulated scoop of M. Leroy. In two instances M. Bégin, (*Elem. de Pathol.*, 2nd edit., p. 521,) has succeeded without any difficulty in extracting cherry pits which had got introduced into the *bottom of the auditory passage*, by means of a small slender iron rod slightly curved in the form of a scoop: a vibratory movement made upon the instrument caused the expulsion of the foreign body.

J. In difficult cases *Paul* made a semilunar incision behind the concha, in order to penetrate to the bottom of the passage, by opening through the cartilage from without inwards, and to be thus enabled to force out the foreign body from within outwards, by means of a suitable instrument. This operation, again recommended by Dionis and Verduc, is now wholly abandoned. It should not, however, perhaps, be entirely rejected when the danger presses, and all other means have been fruitless.

K. *Injections* thrown in with some force, eulogized by M. Dumoustier (*Thèse*, Strasbourg, 1810, p. 5,) and M. Mayor, (*Journ. des Conn. Méd.*, t. III. p. 13,) already employed at the time of Celsus, and censured by Scultetus, and which had been used with advantage by a surgeon of the acquaintance of Morgagni, (*Lettre XIV.*, p. 334. Art. XIII.) would be applicable if the foreign body had but little size, or was light. It is however obvious that the douche and injections through the Eustachian tube, as recommended by M. Deleau, (*Gaz.*

*Med. de Paris*, 1835, p. 303,) could not succeed unless the membrane of the tympanum was ruptured. We must always, moreover, before commencing the operation, and whether we use this or that instrument, instil some drops of oil into the ear, in order to render the parts smoother, and less irritable. Afterwards, nothing remains to be done, except to throw up emollient injections during the space of some days; unless, however, the manipulations made use of should induce us to apprehend the subsequent development of formidable accidents. Under such circumstances, the antiphlogistic treatment with hypnotics and calmants, should the pains be acute, become indispensable.

[*Foreign Bodies—Ear.*—Mr. Carpenter, of Castelcomer, (*Dublin Medical Press*, June 20, 1841,) has met with remarkable success in detaching, and then extracting foreign bodies wedged against the tympanum, in the meatus of the ear, such as garden peas, pebbles, &c., by injecting cold water with force into the passage, by means of a syringe containing two ounces or more. T.]

### § V.—*Polypi.*

A. All the different modes of treatment which have been adopted for polypi of the nasal fossæ, have been prescribed also for those of the ear. Aranzi alleges that they may be cured by means of red precipitate ointment. De Vigo employed by turns for this purpose, the red hot iron, caustics, and the ligature and forceps. Paul removed them with a bistoury made expressly for this purpose, or by means of his pterygotome. G. de Salicet cauterized their root, after having ligated them with a horse-hair or silk thread. The ligature and extirpation are almost the only two methods employed at the present day.

B. *The ligature*, which F. de Hilden, Marchettis and Purmann adjusted by means of a silver plate curved in the form of a forceps, is rendered more practicable, says C. de Solingen, by previously traversing the base of the tumor by means of a thread, as a substitute for an erigne. It is in reality applicable only in a very small number of cases, and for those polypi which have a narrow pedicle and in near proximity to the pavillon. It is executed by means of a hempen thread and the canula of Desault, or by the process of F. de Hilden, as modified by Solingen, or what is still as good, by introducing with the forceps, and causing it to pass in with a probe, a running-knot or noose of the thread as far down as to the root of the polypus. After the ligature is placed, by whatever mode it may be, its two ends are introduced into a knot-tightener, and from this moment the operation has nothing particular.

C. *Excision* is practicable under the same circumstances, and almost in all cases where the ligature may be made trial of. The polypus having been secured with an erigne, we draw it towards us, while reversing it slightly in order to lay bare its root and divide it with one cut of the bistoury. De Lavauguyon, B. Bell, &c., who prefer this to the other methods, have not found it necessary in order to perform it, to make use of the hook-shaped knife of F. de Hilden; but it is evident that the narrow, blunt-pointed scissors, which are slightly curved flatwise, could be advantageously substituted for the bistoury.

D. As to arrachement, the only method in my opinion which can be advantageously applied to polypi whose roots are deeply situated, and which, if necessary, would answer also for the others, it may be effected by means of the ordinary hooks, and the eyed scoops, which are thin and garnished with teeth. The *speculum auris* of G. Fabricius, that of Cleland, as well as all those which have been proposed before and since are useless, if not injurious. Hooks now take their place. The surgeon opens them gently, inserts them between the tumor and the walls of the canal, which he carefully dilates; causes them in this manner to glide as deep within the cavity as possible, and when the polypus is firmly seized he turns them upon their axis, and then tears out the whole with a half drawing and half twisting motion. The blood which escapes at the moment conceals the parts to so great a degree, that in most cases we are obliged to defer till the next day the exploration necessary to ascertain whether there exists or not, anything more in the auditory passage. This hemorrhage, however, is never dangerous. A tent of lint besmeared with cerate, or a pledget of lint of the same kind, to prevent the bleeding surfaces from being irritated from contact with the air, form all the dressing that is required, and which moreover is always made use of after extraction of polypi from the ear.

E. However little there may remain of the heterogeneous tissue after the operation, we must endeavor to destroy it, not with the hot iron as recommended by G. de Salicet and F. de Hilden, &c., but by means of caustics, which, in our time, generally have the preference.

The canula of J. de Vigo, which is to have an opening on the side, after the advice of Marchettis, Verduc, &c., enables us, it is true, to apply the cautery exclusively upon the diseased point; but as we are sometimes under the necessity of acting upon large surfaces, or very near the membrana tympani, the actual cautery must here necessarily be attended with some degree of danger. Nothing, on the contrary, is more simple than to reach the polypus through the same canula by means of a hair-pencil besmeared with butter of antimony, nitrate of mercury or any other caustic, even supposing that the lapis infernalis could not be substituted for these different articles. Instances of polypi of the ear cured by extraction have been also related in the Clinique of M. Pl. Portal, (vol. I., p. 265, 366.)

F. *Polypi of the ear are so slowly developed*, and produce so little disturbance of the functions in certain subjects, that many patients have them for years before asking to be relieved of them. In February, 1830, I extracted one at the hospital of St. Antoine in an adult man, in whom it had existed for fourteen years. Their extraction in such cases is not unattended with some danger. The tympanum, which has been shut out for a considerable length of time from the action of its appropriate stimulants, would be irritated by their presence if they were removed without caution. It is the same as with an eye which has been operated on for cataract: it must be first kept in darkness and not afterwards be exposed to the light except by imperceptible degrees.

G. *Polypi of the ear sometimes acquire a considerable size*: that

mentioned by Sussius (Gerdv, *Thèse de Concours*, 1833, p. 144,) exceeded the size of the fist. A woman whom I had for some weeks at the hospital of La Charité in 1838, had one which was scarcely less in size. I saw the same thing in a young man in 1837. In a female aged twenty-nine years M. Itard (*Mal. des Oreilles*, t. II., p. 125,) found one which was an inch and a half long; but it is not clear that many of these unusual examples did not belong to the class of sarcomatous fungi, either of the dura mater or neighboring bones. In order to remove a tumor of this description in 1835, in a peasant aged twenty-seven years, I was obliged to slit up the pavillon behind, transversely, then to have recourse to a small knife, curved on its flat side, in order to detach the tumor from the bottom of the cavity of the tympanum; I then saw that the fungus did not stop in its limitations in the ear, and that it would repullulate. The patient having survived, I cannot say if, in this case, the dura mater was in reality the source of the disease.

## ARTICLE II.—INTERNAL EAR.

### § I.—*Perforation of the Membrana Tympani.*

Plemp is the first, I believe, who has maintained that the function of hearing may continue although the membrane of the tympanum has been perforated. The fact he relates in support of his assertion appeared at that time so extraordinary, that Verduc refuses to place confidence in it, while Valsalva, who speaks of experiments made upon animals, also denies its possibility, in spite of the authority of Riolan, sustained upon the example of a deaf mute, who having plunged an ear-picker through it, immediately regained his hearing.

Cheselden went farther; since, says he, the loss of the membrana tympani does not produce deafness, we might perhaps, by perforating it in some persons re-establish the faculty of hearing. Unfortunately his operation was unattended with success in the criminal upon whom he first put this suggestion into practice. Though again pointed out by Portal, and formally recommended by Busson, as a means for evacuating abscesses of the cavity of the tympanum, perforation of the tympanum could not be rescued from oblivion, but by M. A. Cooper, who first practised it successfully as a remedy for deafness in 1800 and 1802. Since made trial of with different results by numerous surgeons, it is again ranked among the useful and systematized operations of the healing art. A small curved trochar is the only instrument that was used by M. Cooper, who in order to avoid touching the malleus and the chorda tympani, properly advises that we should perforate the membrane at its anterior and inferior fourth.

Himly, who pretends to have publicly described this operation in 1797, states that the opening soon closes up when we use the trochar. In order to avoid this inconvenience we may perform it with a punch, which M. Fabrizi, of Modena, (*Journ. des Progrès*, t. VII., p. 153,) has ingeniously simplified. After this remark, the cataract needle preferred by Arnemann, the small square-shaped knife as well as Hey's needle, with which Buchanan proposes to divide the fibres of the membrane transversely, and thus favor the retraction of the lips of

the wound, together with the triangular sound of Paroisse and the concealed kystotome of Fusch, ought to be proscribed, as well as the small stilette armed with a circular shoulder near its point, invented by M. Rust, the knitting needle, which according to Michaelis might equally be adopted, the simple probe of Itard, the needle that Saissy incloses in a small gum-elastic canula, and the kystotome of La Faye, which to myself appears to be more convenient than any other instrument. Finally, it was also with a view of having a permanent opening, that M. Richerand supposed that it would be better to perforate the tympanum by cauterizing the membrane with a crayon of nitrate of silver, and that Zang suggested the idea of leaving a catgut in the wound.

To the three successful cases of A. Cooper, we must now add a great number of others. Those of Ansiaux, (*Clin. Chir.*, p. 260, 2nd edit.) and of Sanders for example, who has cured a deafness of three years' standing by means of this operation; another of Paroisse, in a patient who had been deaf for eight years; those of Michaelis, M. Rust, Itard, Saissy, Maunoir, and Herhold, which latter states that he succeeded in two cases out of three; and those of M. Fabrizi, who informs me he has cured in more than ten instances; but we must not however dissemble that most of those practitioners, as Celliez and Itard among others, and Dubois, in four different trials, have also performed it without deriving the slightest benefit from it. Trury and Kauerz have not been, I believe, any more successful. It is moreover applicable, but in a very small number of cases. We should be wrong therefore to expect any benefit from it when the cause of the deafness is found to be a lesion of the labyrinth, or of the middle portion of the ear, or of the nerves or small bones, or of their muscles; in a word, wherever the disease does not consist merely and simply in the obliteration of the Eustachian tube, or in a thickening or any degenerescence whatever, of the membrane of the tympanum itself. Its object in fact, is to admit the air to enter into the cavity of the tympanum and the mastoid cells. Pus, serosity, mucosities, and other liquid matters, of which it might also favor the egress, would not require this operation unless there should not exist the more natural route through the pharynx. Moreover, it is not dangerous, nor does it give rise to very serious accidents. Being attended with scarcely any pain, and rarely followed by a general reaction, there is no objection to making trial of it when we have no longer any thing to hope for from other remedies; only that we must not promise ourselves too favorable results, or build too sanguine hopes upon it. The simple puncture moreover is of no service. The aperture often closes upon the following day. Excision itself, when a proper instrument has not been at command, is not free from this inconvenience. M. Deleau's punch, which is a kind of concealed spring which slackens at the pleasure of the operator, and which suddenly pushes against each other two small circles with sharp cutting edges, in such manner as to detach a perfect disc from the tympanum, though one of the most perfect instruments, is still far however from being always attended with success. There is scarcely any instrumental apparatus than that of M. Fabrizi, which will in this respect fulfil every indication.

§ II.—*Perforation of the Mastoid Cells.*

A. When, in consequence of inflammations that are acute or even chronic, severe, dull, or tensive pains are found to exist in the ear,—when we have strong reason for believing that an abscess has formed in this part,—that injections into the cavity of the tympanum would be advantageous, or that there are some carious bones or splinters to be removed, perforation of the mastoid process appears to be very clearly indicated. The passage in which Galen says that where ulcers of the auditory canal have altered the hard parts, we must make an incision behind the ear and rasp the bones or remove their splinters, is all that we find in the ancients that appears to have reference to this subject. But Valsalva had already made the remark that injections forced into the mastoid cells come out by the mouth. Riolan and Rolfinck expressly mention trephining the mastoid process. Heuermann, who saw an abscess of the ear make its exit in that part, and leave a fistula there, concluded therefore, like Duverney in speaking of the surgeon Deymier, that the best thing to be done in such cases would be to apply the crown of a trephine behind the concha, without giving time for the pus to make too profound an alteration in the spongy texture of the process. A patient who would not submit to this operation, recommended by J. L. Petit, died, while by means of it the same author cured a certain number of other patients who were at least as severely affected. Observations of the same kind have been published by Morand, Leschevin, J. Frank, Martin, &c. It is principally upon these that Jasser justified himself in operating upon the soldier, in whom he opened the mastoid process on one side, containing an abscess with caries, and that of the other side in consequence of a simple deafness. Fiedlitz has performed this perforation successfully on both sides in a woman, who had been rendered deaf by a quartan fever. The same author, as quoted by Richter, relates two other cases not less remarkable. Laeßler, who eulogizes it greatly, recommends that we should make use of a perforating trephine, armed with a border, which prevents it from penetrating too deep; that we should incise the soft parts twenty-four hours before perforating the bone, in order to have no blood effused into the mastoid cells; and that finally, we should make use daily of injections into the opening, which is to be kept open and dilated by means of a leaden sound. Hagstroem, who however has had no reason to be satisfied with this operation, enters into many more details upon the mode of performing it than Laeßler, whose ideas he for the most part adopts. If there already exists a fistula, he says we should confine ourselves to enlarging it. Otherwise we lay bare the bone while avoiding the auricular artery, which is naturally nearer to the concha; after which we have nothing more to do than to perforate the process from behind forwards, by means of a drill, a punch, or a trochar, rather than with a perforator. Acrel considers trephining the ear useless when the bones are sound, and Murray has very properly observed that before the age of puberty, as the mastoid cells are scarcely then developed, it could in reality then be attended with no advantage. The case of Dr. Berger, who died after having been operated upon by Koelpin, and in

whom no cells were found, proves that they may be wanting also in some adults. Similar facts related by Morgagni, however, did not deter either Proet or Arnemann, who assure us that they have had recourse to it with success. Hydropsy of the cavity of the tympanum and simple abscesses do not absolutely require it. They are evacuated full as well by perforating the membrane of the tympanum, which is infinitely less painful and less severe. It is only after all in collections of pus, accompanied with necrosis or caries, and which have a tendency to open behind the ear, that we are to some extent obliged to have recourse to it. In a case of this description, M. Weber, who found the mastoid process sound, after having trephined it, nevertheless cured his patient. M. Denonvilliers, (*Thèse d'agrégat.*, &c., 1839, p. 72,) in analyzing fourteen of these operations on nine patients, found nine cases of cure, two of amelioration, three failures, and one death.

B. *Operative Process*.—A crucial or T incision lays bare the whole outer surface of the mastoid process; we then apply to it either a perforator, or a small crown of the trephine, a drill or a trochar. We take care to slightly incline the instrument forwards and upwards in proportion as it penetrates. As soon as it arrives at the auditory cells we withdraw it, in order to enlarge the opening, if it is necessary, before we stop. Injections are then forced into it with caution. Tents, or rolls of lint, or a leaden sound, should be placed daily in the perforation until the cavity of the tympanum is restored to its natural state. The chisel, gouge and mallet, which were used by J. L. Petit, Chopart and Desault, ought to have the preference, if the bone should be extensively necrosed and it were necessary to remove from it large sized fragments. Should nothing beforehand indicate where the instrument ought to be applied, it should be inserted at six or eight lines above the point of the process. The largest cells correspond to this part. The auricular artery, which is found in front, and the submastoid artery, which is below, may be easily avoided.

### § III.—*Catheterism of the Eustachian Tube.*

A. The idea of penetrating into the cavity of the tympanum through the pharynx, is one that is already very ancient. Archigenes, Valsalva, Munnicks and Busson no doubt had this in their minds when they recommended to inhale vapors of water, tobacco, or other substances, and to forcibly close the nose as well as the mouth, in order to force them to pass towards the ear during expiration. In the year 1724 Guyot, maitre de poste at Versailles, and Cleland in 1741, each devised an instrument for injecting the Eustachian tubes, the one by the mouth, the other through the nose. The sound of A. Petit, which is slightly curved, rendered the operation still more easy. Douglas and Wathen pronounced in favor of the process of Cleland. Heuermann and Ten Haaf adopting that of Guyot, introduced through the mouth into the Eustachian tube a female catheter above the velum palati, and afterwards screwed a small syringe to the other extremity of this instrument. Again recommended by Falkenberg, Sims, Chopart and Desault, and by Callisen, who sometimes performs it through the nose and sometimes through

the mouth, and describes its steps very accurately, and by Buchanan, Itard, Boyer, Richerand, &c.; and proscribed as inapplicable to living man by B. Bell, and by Trempel as dangerous; these injections have again been brought into repute and warmly extolled by M. Deleau. As a mechanical means they enable us to clear out the tubes; and as a medical remedy they act with efficacy on inflammations and engorgements of every description, and on inspissated matters and collections of liquids in the cavity and guttural duct of the tympanum. It may be conceived then how important they would be in deafness, which depends upon one of these causes.

B. There is no doubt *that we may penetrate into the tube through the mouth* by means of a curved sound above, behind and upon one of the sides of the velum palati, as was done by Heuermann; but the operation being still more easy and especially more certain through the *nasal fossæ*, it is this route which, at the present day, is generally preferred. *Saissy's instrument*, *Itard's* sound in the shape of an Italic S, or a catheter, which differs from a female one in this only, that being open at its two extremities, it has no apertures upon its sides, are with a small syringe to force in the liquids, all that are required for such an operation. A gum-elastic catheter provided with its stilette and properly curved; or a blunt-pointed probe in case it were requisite to overcome the obstructions with a solid instrument, might in a case of necessity be substituted for the other catheters. The surgeon being placed on the side and in front of the patient, reverses the head with one hand, seizes with the other a catheter besmeared with some unctuous matter, presents its beak at the orifice of the nose and causes it to slide along upon the floor of the nasal fossæ at the lower part of the meatus, taking care to keep the convexity of the instrument turned towards the side of the septum and slightly inclined upwards. Having arrived at the upper side of the velum, he slightly elevates the extremity of the instrument without permitting it to leave the external wall of the nostril, which obliges it gradually to reach the upper part of the maxillary meatus; continues to push it in this direction, and inevitably falls into the pavillon of the tube, which from that point runs obliquely outwards, backwards and upwards. As soon as the catheter has entered sufficiently far, the syringe is adapted to its outer extremity, as when we wish to inject in hydrocele, after which any person may comprehend what remains to be done. The operation is repeated once or twice daily, and nothing prevents us, as is perceived, from injecting in this manner into the middle part of the ear whatever medicated liquid we may think proper. Should the injection have stopped in the tube and be prevented by any means from advancing farther, we should in this case remove the syringe and introduce a blunt-pointed probe up to the point where the difficulty is, in order to perforate or destroy it. It must be well understood here that force must not be used but with a great deal of caution, and that before having recourse to it we should make ourselves certain that it has become indispensable and that better directed manipulations might not render it unnecessary.

C. M. Deleau, perceiving that the point of the metallic catheter cannot escape from immediately butting against the walls of the tube, as soon as we desire to advance it a few lines, that its inflexibility

creates pain, and that aqueous injections do not penetrate in this manner into the auricular cavity but with considerable difficulty, has proposed to substitute for it a flexible catheter, and to have recourse to the douches of atmospheric air already recommended a long time since by Herhold, (*L'Experience*, t. I., p. 518.) By the processes of this surgeon the operation becomes practicable at every age. I have seen at his residence two young boys, one four years of age, the other seven, accommodate themselves in the readiest way that could be desired to the manipulations of his method, without evincing the slightest indication of pain. By means of a silver stilette four to six inches long, having quite a strong curvature near its extremity, and a ring on the other extremity, and the diameter of which instrument varies from half a line to a line and a half, he conducts a gum-elastic catheter into the tube. The patient being seated upon a chair, holds his head slightly reversed either against the back of the chair or against a cushion for this purpose, which supported upon an upright may be elevated or depressed at pleasure. The operator, armed with the instrument, which has been previously oiled, presents it at the nostril while holding it in his right hand, like a writing pen, with the concavity turned downwards and outwards. Causing it to penetrate rapidly while following the floor of this cavity, he soon reaches the velum palati, (which is indicated to him by an involuntary movement of deglutition, and the extent of two inches or two inches and a half, at which he has entered,) and immediately elevates the beak outwardly and upward by a circular or rotatory movement, in order to enter into the tube. Seizing with the thumb and forefinger of the left hand the free extremity of the catheter above, he endeavors, if it has stopped, to make it advance, while the stilette is kept immovable by means of his right hand; proceeds in this manner till he reaches the obstacle, which he overcomes in the same manner that we would a contraction of the urethra, and withdraws the directing stilette as soon as he thinks he has entered sufficiently far. A silver pavillon is immediately screwed upon the external opening of the canula, which the surgeon keeps in its place by means of a metallic wire which is passed around it in the manner of a forceps, and which embraces at the same time the ala of the nose. Adapting to this pavillon the beak of a syringe, or bottle, or ball of caoutchouc, he uses this to force the air beyond the obstruction, not exceeding a degree of pressure which habit alone can enable him to estimate. By applying our ear to that of the patient, we perceive whether the cavity of the tympanum is sound or altered, empty or full, and whether the air which we have forced into it can or cannot come out from it between the catheter and walls of the tube. Substituting for the syringe the pipe of a reservoir provided with a manometer, and in which a pump does the duty of compressing the air, and then opening the faucet of this apparatus, we establish in this manner a double atmospheric current in the ear, one which enters by the catheter, and the other which issues out between it and the guttural duct; the operator, who has the power to augment or diminish the force of this douche, intermits it at the expiration of one or several minutes.

D. In order to penetrate through the other nostril, the instrument is to be a little more curved, with its beak slightly reversed in the

direction of its convexity. Being held in the same hand, with the concavity turned downwards and inwards, it is made to pass along the inferior border of the septum. Having arrived at the velum palati, the hand is elevated and carried outwards to incline the extremity of the instrument behind the vomer, that it may reach the tube. The rest of the process is performed as in the preceding one. In both cases, if the catheter is not properly in its place, the patient himself notices it when he has once undergone the operation.

Its direction and the manner in which it is maintained, moreover, sufficiently point it out to the surgeon. He possesses however a ready means of satisfying himself with certainty. Having withdrawn the stilette, we have nothing to do but to force in the air or liquid by the canula. The injection will fall into the pharynx if the position is false, and will not penetrate, or, in the contrary case, will enter into the cavity of the tympanum. If after having overcome the obstruction, the air produces in the cavity a *pattering sound* (*bruit de pluie*) upon the membrane of the tympanum, or a rough sound (*bruit sec*), we conclude from this that the middle part of the ear is not altered; if it seems rather to agitate a liquid, and if the sound is *muco*se, (*muqueux*), we are then authorized in believing in the existence of pus, blood, serosity or at least an engorgement of the internal membrane of the middle ear.

In both cases, if the tube is evidently choked up or narrowed, and that the patient perceives sounds better immediately after than before the catheterism, the deafness is imputable to the condition of the tube and there is every reason to believe that it may be cured. When there results no change from it, the disease is very probably elsewhere, and we may be almost certain that this operation will be of no advantage afterwards. If acute pain be produced by the injection, it indicates an acute phlegmasia or too great a degree of nervous irritability, which are to be treated by means of the usual remedies. In simple obstruction or phlegmasias that are purely chronic, the suffering is almost nothing either during or after the operation. M. Deleau explains the action of the air in a manner which is altogether mechanical. It ventilates, fumigates and washes out gradually the cavity of the tympanum and the mastoid cells. In returning between the catheter and the tube, it necessarily makes an effort, and becomes a dilating and resolvent body by the compression which it exercises upon the engorged tissues. Water and liquids are much more liable to wound and lacerate the membrana tympani, &c., and do not produce medical effects different from gases. Any intelligent person may understand after all that every case must require particular modifications, and that in respect to the operative manual it is the same with contractions of the Eustachian tube as with the coarctations of the urethra; and that on this point, address and trials often repeated, joined to much prudence, will be alone enabled to give sufficient degree of dexterity to the person who would desire to employ with advantage catheterism of the guttural duct of the auditory apparatus.

E. The sounds, catheters and probes devised by M. Gairal, (*Journ. Hebdom.*, 1836, t. II., pp. 97, 129, 197,) who provides them with a leather bottle and faucet (*une outre à robinet*), and of gum

elastic, in order to inject the Eustachian tube, render the operation still more easy and perfect.

F. One doubt remains for me to express: the engorgement, thickening, and inflamed condition of the mucous membrane of the tube being admitted as a cause of deafness, would it not be allowable to make use, against these affections, of the treatment which is advantageously employed for their radical cure in the urethra, to wit: cauterization with nitrate of silver? Having made no trial in support of this suggestion, I merely recur to it, en passant, and am not unaware of the apprehension that ought naturally to be inspired by the introduction of caustics into the ear through the pharynx.

I will add that the attempts made by different persons since the first edition of this work, have not yet produced any very satisfactory result, and that the excision of the tonsils is likewise a valuable means in the cure of this description of deafness.

## PART SECOND.

### OPERATIONS WHICH ARE PERFORMED UPON THE NECK.

#### CHAPTER I.

##### TUMORS OF THE SALIVARY REGIONS.

##### ARTICLE I.—THE PAROTID, AND PAROTID TUMORS.

##### § I.—*Examination of Facts.*

Should we take literally what authors of the last century have said of it, nothing could be more simple than the total eradication of the parotid gland. In our times, on the contrary, nothing seems to be more uncommon, so much so that numerous distinguished surgeons, Boyer among others, deny even its possibility.

It is true that most of the cases which have been related are far from being conclusive. Thus, as Richter had already remarked and as Burns has demonstrated, the assertions of Heister, who says he had often extirpated the parotid; those of Scultetus, Verdier, Palfin, V. Swieten, Gooch, Berh, Roonhuysen, Gottefried, Errhart, &c., and of Garengéot, who pretends that this operation scarcely ever causes any hemorrhage; of Scharschmidt, who considers that he has performed it a great number of times with success, among others, upon a patient in whom the tumor weighed three pounds; of Acrel, who was enabled to arrest the hemorrhage by means of simple tamponing; of Burgraw and Hezel, and of Alix, who was enabled to extirpate a mass of four pounds in weight below the ear, without producing the slightest effusion of blood; of K. Boerhaave, and some others still, evidently refer to the ablation of lymphatic tumors developed in the depth of the parotid space, or to cysts either salivary,

as in the case of M. Krimer, (*Bull. de Fér.*, t. XVI., p. 72,) or purely serous, as in the patient of M. Henri, (*Bull. de l'Acad. Roy. de Méd.*, t. I., p. 56,) and not to the parotid itself. M. Smith, (*Gaz. Méd.*, 1839, p. 43,) who considers that he extirpated the parotid, in removing from the parotid depression a tumor of the size of a nut, and who divided the facial nerve, took away probably only a degenerate lymphatic mass. The tumor of the size of an orange, successfully extirpated by M. Goyrand, (Savournin, *Lancette Franc.*, 1839, t. I., p. 14,) from the parotid region, was not the gland. In another case the same surgeon, (*Lancette Franc.*, 1839, t. I., p. 14,) removed a part of the parotid gland, and the submaxillary gland, together with degenerated lymphatic ganglions. The patient got well without any unpleasant consequences. It would be doubtless difficult to say whether the tumor successfully removed from the parotid region by M. Pl. Portal, (*Clin. Chir.*, vol. I., p. 125,) was rather of an encephaloid than lymphatic nature; but certainly it was not the gland itself. In 1781, J. B. Siebold supposed that he had removed the parotid entire, because after the operation it could be readily seen that the digastric and stylo-hyoid muscles, as well as the carotid artery, were laid bare. In a student mentioned by Heister, it became necessary to go so deep, that the carotid gave rise to a fatal hemorrhage. Soucramp, supposing that he was about to remove a loupe, discovered that he had extirpated the parotid. There was much less blood discharged than the surgeon expected, and the patient was perfectly restored. In 1796, Ch. G. Siebold, who removed an enormous tumor from the side of the neck in a young girl, states that the cavity thereby made was so deep that all the assistants were obliged to admit that the parotid had been extracted from it entire. In the patient operated upon by Klein (*Graefe und Walther's Journ.*, vol. I., p. 106) in 1820, the facial nerve was divided. The cure was accomplished at the expiration of eighteen days. In the case of M. Idrac, there was no artery requiring a ligature; but the wound presented the same aspect as in the patient of Siebold the father. The case recovered without being followed by paralysis. The case of M. Lacoste differs from that of M. Idrac in this only, that there was an abundant hemorrhage, which was twice renewed, and placed the life of the patient in jeopardy. One of the tumors removed by M. Prieger, (*Ibid.*, vol. III., p. 455,) weighed nearly three pounds. The carotid was avoided and the woman survived. If we may believe M. Kirby, he was enabled to satisfy himself, after his operation, that the interval between the pterygoid muscles was void, and the auditory passage laid bare, as well as the temporo-maxillary articulation, and the whole length of the styloid process. Nevertheless, tamponing with sponges succeeded in arresting the hemorrhage, and notwithstanding an erysipelas which appeared on the face, the patient recovered. As to the fact related by M. Pamard, the author himself admits that the parotid was not extirpated in its totality. M. Nægèle, on his part, alleges that we may remove this gland in the dead body without wounding the facial nerve, and maintains that he performed it with success without producing paralysis. M. Moulinié, (*Bull. Méd. de Bordeaux*, 1833,) having cauterized after having excised or extirpated the tumor, lost one of his patients and cured the other. In a pa-

tient whom I have seen and who was first successfully operated on by M. L'Herminier of Guadaloupe, the cancer reappeared and caused death. Goodlad furnishes a case which is sufficiently well detailed, of extirpation of the parotid; it is to Béclard, however, that we are indebted for the first demonstration of this fact. His patient, who was operated upon in 1823, had all the muscles upon one side of his face paralyzed, and as he died some months subsequently, they were enabled to ascertain that the whole gland had been actually extirpated. A patient operated upon in September, 1824, by M. Gensoul, and who died in the course of the year 1825, also furnished the proof that the parotid had been thoroughly extirpated. M. Gensoul, still more fortunate than in his first case, repeated this operation in 1826 with entire success; but the patient remained paralyzed on one half of his face. M. Carmichael had been equally fortunate some time before, that is to say in 1818, and mentions the same peculiarity as M. Gensoul as the consequence of the operation.

In 1826, also, M. Lisfranc had occasion to remove the parotid, and ascertained, after death, that scarcely anything of the gland remained in the parotid space. M. Mott, (*Arch. Gén. de Méd.*, t. XXX., p. 419,) who previously tied the carotid, also considers that he extirpated the whole gland in a patient, who died at the expiration of seven weeks. M. Roux (*Ibid.*, 2e série, t. VII., p. 404,) and M. Chelius (*Ibid.*, 2e série, t. IX., pp. 230, 265,) in performing the same operation did not find it necessary to tie the carotid artery. In the operation performed by M. Heyfelder, (*Graefse und Walther's Journ.*, vol. X., p. 575,) in the month of June, 1825, the patient lost but three or four ounces of blood, a small lobe of the gland only was left in front, and the paralysis of the face ultimately disappeared spontaneously. In the patient operated upon by M. MacLellan in 1826, the cure was complete, says the author, though the gland had been entirely removed. That of M. Cordes, (*Journ. de Walther, &c.*, vol. II., p. 105,) who states that he did not leave the least particle of the gland, also perfectly recovered. M. Bernt (*Bull. de Fér.*, t. III., p. 287,) also alleges that he has performed this extirpation with success. The Archives (*Arch. Gén. de Méd.*, t. IV., p. 64,) contain another example, in which layer after layer was removed down to the carotid. In the operation which M. A. Fontheim (*Graefse und Walther's Journ.*, vol. XIII., p. 290,) performed in the month of November, 1828, the carotid was not wounded, no hemorrhage supervened, and the cure was completed on the thirtieth day. The paralysis itself, which took place at first as in the preceding cases, completely disappeared. In the month of January, 1829, M. A. Magri (*Bull. de Fér.*, t. XXII., p. 84, and *Journ. des Progrès*, 2e sér., t. I., p. 261,) extirpated on the side of the neck a tumor which included the whole of the parotid, and was enabled to dispense with a ligature on the trunk of the carotid. The patient was restored in the space of twenty-six days, with the exception, however, of the facial paralysis which remained. M. Dugied, who gives an extract from most of these cases, and which are mentioned also by MM. Hourman and Pillet in their dissertation, also states that MM. A. Cooper and Weinhold have repeatedly extirpated the parotid entire. But I have not been able to ascertain where these

observations have been published, with the exception of those of M. Weinhold, (*Bull. de Fér.*, t. VI., p. 242.) who has preserved one of these glands in his museum and shows it to those who wish to see it. To the examples above mentioned it would be necessary at the present time to add the following:

1st. Man, forty-six years of age; extirpation without previous ligature; no serious hemorrhage; cure; palsy of the face; (Hendriks.) 2nd. Woman, nineteen years of age; extirpation without previous ligature; cure; palsy of the face; (Hendriks.) 3d. Woman, thirty-eight years of age; extirpation without previous ligature; cure; (Hendriks.) 4th. Woman, thirty-three years of age; extirpation and cauterization; cure; (Hendriks.)—(Baamberg, *Dissert. sur l'Extirp. de la Parot.*) 5th. A woman; size of a goose egg; extirpation; cure; (Eulenberg;) (*Journ. des Conn. Méd-Chir.*, t. III., p. 75.) 6th. Another; enormous; previous ligature of the carotid; (Stedmann;) (*Gaz. Méd.*, 1832, p. 529.) 7th. Another; prolonging itself upon the jaw; ligature of the carotid; cure; (Ayll;) (*Western and Physic. Journ.*, vol. I., p. 423.) 8th. Another; (Eckstrum;) (*Bull. de Fér.*, t. VIII., p. 204.) 9th. Another; boy, aged fifteen years; ligature upon the external carotid; apprehension of a return. 10th. Another; extirpation incomplete; (Ansiaux;) (*Clin. Chir.*, p. 233, 2d edit.) 11th. Another; extirpation without previous ligature, and cure; (Warren, the father.) 12th. Another; the carotid wounded and tied; fistula and paralysis; (Warren, the son;) (*On Tumors, &c.* p. 280.) 13th. A woman; thirty-four years of age; on the right side, and weighed twenty-one ounces; performed 26th May; cured. 14th July, 1838; (MacGregor;) (*Lancet*, June, 1838, p. 498.) 14th. Another; the jugular [wounded] and external carotid tied; cured; (Widmer;) (*L'Experience*, t. II., p. 336.)

II. *Appreciation of the Facts.*—The question whether we may or may not extirpate the parotid gland in its totality, appears to me to have been incorrectly stated. The salivary glands, including with them the parotid, scarcely ever degenerate. The tumors that have been removed under their name almost all belong to other tissues and to other organs. Even in the substance of the parotid itself there are a great number of lymphatic ganglions. These ganglions when they swell become fungous, tuberculous, and cancerous, and are transformed into bosselated tumors, which spread out, flatten, and disorganize the glandular tissue, and lead to misconceptions of the real character of the parts which are extirpated. I have performed extirpations of this kind at least twenty times, to such extent as to lay bare the whole parotid cavity, and to be afterwards under the necessity of submitting the tumor to a careful dissection, in order to satisfy myself that the ganglions, rather than the glands, had been the source of the disease. I have, moreover, encountered in this region meliceromatous, lipomatous, fibrous, melanotic, encephaloid, and other tumors. A new-born infant that M. P. Dubois showed me, in Jan., 1839, had in this part an erectile venous tumor of five inches in diameter. Not wishing to treat in this place except of tumors which implicate the parotid, whether they originate or not from its tissue, I refer to the chapter on tumors in general for those of other descriptions.

§ III.—*Anatomical Remarks.*

The parotid, enveloped in its aponeurosis, continuous in some respects with the sub-maxillary gland, as it passes upon the internal side of the angle of the jaw, united superiorly in quite a firm manner to the auditory passage and behind to the mastoid process and sterno-mastoid muscle, is prolonged in front upon the external surface of the masseter. On its anterior surface it covers or includes among its lobes from above downwards and from without inwards;—1st, the transverse facial artery and the two principal branches of the facial nerve at the point where they pass upon the border of the jaw; 2d, parallel to this border the superficial temporal artery and vein; 3d, the external carotid and the origin of the internal maxillary artery; and 4th, the pterygoid muscles and some branches of the pharyngeal vessels. Inferiorly it rests against the stylo-maxillary ligament and the digastric and stylo-hyoid muscles; posteriorly between the ear and mastoid process against the auricular artery; and deeper still upon the stylo-mastoid artery. At its apex it reaches nearly to the internal jugular vein, and the great hypo-glossus, pneumo-gastric, and great sympathetic nerves, between the transverse process of the first vertebræ and the pharynx. One of its branches is almost always prolonged between the two carotids. Another frequently reaches between the stylo-glossus and stylopharyngeal muscles, the internal carotid artery and the jugular vein. All of them cover the styloid process, which they embrace, and the root of the anatomical bouquet of Riolan. Finally, it is traversed obliquely from above downwards, from within outwards, and from behind forwards, by the trunk of the facial nerve, which bifurcates in its substance, where is encountered also the vein which makes the communication between the two jugulars, some very small lymphatic ganglions, and other arterial and venous branches much less important.

§ IV.—*Operative Process.*

When the operation is decided upon, the first question which presents itself, is this: should we or should we not imitate Goodlad, who was among the first that tied, as a preliminary step, the carotid artery? In the beginning we never can know whether we shall be under the necessity of removing the gland in its totality. Though the wounding of the external carotid is almost inevitable, the internal carotid may in a great many instances be respected. In making up our minds to surround the trunk only with a thread during the progress of the operation, as was done or appears to have been done by Bèclard and MM. Carmichael, Gensoul and Lisfranc, we have, if it is practicable, the chance at least of dispensing with the ligature, and without exposing ourselves on that account to the encounter of more serious difficulties than by any other process. The surgeon finding that the glandular tissue instead of having produced the disease has merely become the receptacle of it, endeavors to remove the gland only in the manner of cellular tissue, which surrounds or is in the vicinity of any tumor whatever; it is to the lymphatic or cancerous tumor, and their branches wherever they may be, that he directs his attention, in place of following out the pro-

longations of the parotid gland. Setting out upon this principle, I have never been under the necessity of tying the carotid vessels beforehand, though I had penetrated down to the bottom of the parotid cavity.

A. *Extirpation*.—The *instruments* that we may require for extirpating parotid tumors, are composed of a straight, convex, and blunt-pointed bistoury, straight and curved scissors, a dissecting forceps, a canulated sound without any cul de sac, a scalpel, the flattened handle of which may serve to separate the parts, should occasion require, needles armed with ligatures, and whatever it would be requisite to have at hand, if we were obliged to place a ligature upon the carotid artery. The rest of the articles consists of sponges, small balls and plumasseau of lint, agaric, long and square compresses, one or two bandages, and other articles which are required in all great operations.

I. *First stage*.—The patient being placed upon his sound side and held by assistants, is to be fixed in such manner as to be enabled to breathe and spit freely. One of the assistants should hold himself ready to compress the trunk of the primitive carotid in case of accident. The size and form of the tumor, and condition of the integuments, determine the kind of incision which is to be first made. If the skin is sound and free from adhesion, if the body to be removed does not exceed the dimensions of a pullet's egg, the crucial or T incision might be replaced by the semilunar, to which for myself I give the preference. Otherwise we must have recourse to the elliptic incision, in order to remove with the tumor a flap of cutaneous tissue of greater or lesser extent. In this last case nothing prevents us from making afterwards upon each lip of the ellipse another incision, which transforms it into a legitimate T, and which after the operation will reduce the whole to a crucial incision. Unless the disease should have extended to a great distance towards the mouth, there can be no doubt that there is less advantage in placing the great diameter of the wound transversely, as Goodlad did, and M. Fontheim advises, than from above downwards. These are the only general rules that are required to be laid down on this first point. It is upon himself and upon his personal knowledge and skill that the operator will be obliged to rely, in order to follow them out, or to modify or restrain them.

II. *Second stage*.—The integuments having been dissected, and the flaps reversed, the surgeon detaches the altered mass by commencing at its superior part, then going to its posterior border, in order that he may not at the beginning fall upon the carotid; he ties the arteries in proportion as they are opened, or if they are of little size confines himself to their compression by the finger of an assistant, and takes care when he reaches towards the border of the jaw or near the pterygoid muscles, to hold the cutting edge of his bistoury rather turned backwards than forwards, and directed rather against the tissues to be extirpated, than towards those which are to be preserved. The handle of the scalpel ought to be preferred so long as it appears to answer. By means of this instrument we detach or isolate the most of the lobes of the gland or tumor, disengage them from among the vessels without incurring the risk of opening the

arteries, and thereby diminish to the same extent the danger of the operation. When, however, we are satisfied that the adhesions to be destroyed do not include any part which it is important to preserve, the bistoury should be substituted for the scalpel. By tearing out the lobes the dissection is more safe; by incision it is less painful, and more favorable for the subsequent symptoms.

III. *Third stage.*—Having arrived behind the maxillary branch, the operator should double his precautions. There are to be found the external carotid and the origin of the temporal and internal maxillary arteries. Deeper still at the top of the parotid fossa, should there exist some pedicle or prolongation, which cannot be detached by the handle of the instrument, prudence suggests that we should apply the ligature to them on the side towards the sound parts, before excising them. On the supposition, that during all these manipulations a large artery, the external carotid for example, has been opened into, or that we perceive that its lesion is inevitable, we ought, before going any farther, to lay it bare near its root, in order that we may apply the ligature to it sufficiently low down not to incur the risk of wounding it afterwards. Should not the muscles of the styloid process, nor especially the digastric be degenerated, we should do all in our power to avoid destroying them. Under opposite circumstances we should sacrifice them without any hesitation, as well as the trunk of the facial nerve, which it is useless to attempt to save when the whole parotid is disorganized. Finally, it may be possible that the tumor no longer resists except at its summit, and that in spite of the tractions made upon it by the left hand on the one part, and by the handle of the scalpel on the other, this point adheres firmly to the bottom of the wound. In this case, from the apprehension that it may include some large vascular trunk, it is better to embrace it with a ligature, strangle it in the same way that we would a polypus, in conforming to the advice of Hezel, and to restrict ourselves for the time being, to the excision of that portion of the tumor only, which remains perfectly free. M. Bégin, (*Elem. de Pathol.*, &c., t. I., 2d edit., p. 204,) from having on one occasion neglected to adopt this precaution, found a volume of arterial spouting from the wound, which gave him so much the greater uneasiness, from the retracted end of the vessel having escaped from the ligatures, and from the necessity to which he was compelled of having recourse to a methodical, severe and painful compression.

IV. *Fourth stage.*—The arteries which may have been wounded are, besides the carotid, the transverse facial, temporal, auricular, mastoid, stylo-mastoid, occipital, internal maxillary, the inferior pharyngeal, and even the lingual and facial. All these branches therefore are to be successively tied, if we have not performed this operation upon their common trunk at first. The blood which continues to flow afterwards can come only from veins, and requires, if it does not stop of itself, no other means than tamponing. At the first aspect the excavation which has been produced has something frightful in its appearance; but its depth alone would not prove that we had in reality extirpated the parotid rather than the lymphatic ganglions. If the wound should only be some inches in extent, its flaps could be approximated and united either by strips of adhesive plaster or the

suture. But when it is very large, if we attempt immediate and complete union, we incur the risk of purulent collections, and simple or phlegmonous erysipelas, and all their consequences, as we have seen in the cases ascribed to Béclard and many others. After the cicatrization the patient may remain feeble, which he should be apprized of. The movements of the pharynx, larynx, tongue, and even the jaw, sometimes suffer much from this operation, owing to the muscles which have been divided. More frequently still, the section of the facial nerve more or less completely paralyzes the eyelids, ala of the nose, the labial angle, or all the corresponding half of the face.

**B. Ligature.**—The cutting instrument is not the only remedy that has been suggested to practitioners for the removal of parotid tumors. Roonhuysen, who, deterred by the dangers of hemorrhage, had already proposed to substitute the ligature for it, introduced a double ligature deep down through the base of the tumor, and afterwards tied its two extremities separately, the one above, the other below, in such manner as to produce mortification of the diseased tissues. M. Mayor recommends that we should first lay it bare as in extirpating it, and that after having isolated all that portion of it which projects externally, we should traverse it in the manner of Roonhuysen, or better still, that we should draw it to the outside as much as possible by means of an erigne forceps, and then introduce upon its root a strong ligature, which he tightens by degrees with his chaplet constrictor. In five or six days, says he, the degenerescence is entirely cut through or reduced to putrilage, and no artery has run any risk of being wounded. It was in this manner that he cured a young girl fourteen years of age of a tumor that she had had for three years in front of the ear; also another patient of eighteen, in whom the gland extended from the zygomatic arch to below the angle of the jaw; finally, a third, in whom the morbid mass, eight inches long and four broad, was situated in the parotid region. But whatever the author may say on the subject, these facts relate much more to the extirpation of degenerate lymphatic ganglions than to that of the parotid gland, properly so called. I find, moreover, an inconvenience in this method: it incurs the risk of removing only a part of the disease when it extends deep within, while, if it is superficial, the employment of the bistoury being then less dangerous, the ligature loses much of its importance. Nevertheless I would not object to make trial of it by combining it with dissection in the first of these cases. Without giving ourselves the trouble of tearing out all the branches of the gland successively, when they penetrate too deep into the midst of the vessels, a strong ligature, which would comprehend them *en masse*, and which would enable us to strangulate them by degrees, appears to me to offer a resource which up to the present time, as M. Mayor justly complains, has been too much neglected.

**C. Caustics.**—The recommendation of Desault and Chopart, who proposed, after having excised all the projecting portion of the scirrhous, that we should destroy the remainder with a hot iron or caustics, is assuredly a much more objectionable process, and scarcely deserves to be taken into consideration. The actual cautery could only be useful in this operation for obliterating the mouths of vessels that had escaped from the ligatures, and for destroying some morbid vestiges,

if there are any, that the instrument has not removed, contrary to the intention of the operator. (See on the subject of cysts or other tumors of the parotid region, and the operations required for them the chapter on *Tumors in general*.)

[CASE OF EXTIRPATION OF THE PAROTID GLAND. By VALENTINE MOTT, M.D., &c. &c. (See *American Journal of the Medical Sciences*, 1832, Vol. X., pp. 17-20.)

J. B., a native of St. Domingo, aged twenty-one years, came under my care in the latter part of June for a tumor situated on the face. He stated that he first observed it in January last, shortly after a severe attack of fever, and that it gradually increased in size until a few months ago, when he became alarmed at its progress, and decided upon visiting this country.

Upon inspection I found a very hard tumor, about the size of an ordinary fist, involving nearly the whole left side of the face, and evidently formed of the parotid gland, apparently in a scirrhus state. (See Fig. 1.) From its magnitude, and as the only chance left for the

(Fig. 1.)

recovery of my patient, I resolved upon attempting its extirpation, and with his free consent, after rendering the subject perfectly intelligible to him, fixed on the 13th of July for carrying it into effect.

Accordingly, on that day the operation was performed. It was commenced by interrupting the circulation through the external carotid artery by ligature, and for that purpose an incision was made from the posterior angle of the lower jaw downward and inward

about three inches in length, so as to expose to view the inner margin of the sterno-cleido mastoid muscle. An enlarged lymphatic gland was now exposed, lying directly upon the sheath of the vessels. Upon turning it to the inside, the external carotid was laid bare, and tied immediately below the digastric muscle, and a little above the upper border of the thyroid cartilage. From the tumefaction of this part of the neck the artery was nearly three inches from the surface.

An incision was next commenced above the jugum temporale and carried downward in a semicircular direction, until it terminated upon the os occipitis. The incision in the neck was now extended upward, to intersect the one over the tumor.

On detaching the integuments in the form of a double flap from over the diseased mass, its black appearance removed the impression of its scirrhus character, and fully demonstrated a melanotic condition of the gland. I however determined upon continuing the dissection, and proceeded to detach it from its various connexions. With this intention I commenced by dividing along the inner margin of the tumor the adipose and cellular tissue, until the inner edge of the masseter muscle was exposed to view. The finger was now introduced into the mouth, and cut upon in order to avoid dividing its membrane, and after separating the tumor for some distance from the masseter, to which it closely adhered, I detached it from the jugum, which had become more or less carious from pressure. It was next dissected from the mastoid and digastric muscles, and from the posterior angle of the jaw, but as the patient complained of excruciating torture when the tumor was raised from below upward, I determined to continue the dissection from above downward, and accordingly separated it, with a few rapid strokes of the knife, from the capsular ligament of the lower jaw, and removed the bulk of the disease, as represented in Fig. 2, next page. The portion filling up the space between the styloid and mastoid processes was cautiously detached with the handle of a scalpel, and the facial nerve or portio dura divided by a quick movement of the knife. At the instant of the division of this nerve, he seemed to evince more pain than at any period of the operation. The muscles of the left side of the face were paralyzed. All the remaining portions of the disease were, as far as practicable, removed.

Several arteries were tied during the extirpation of the tumor, and after its removal. The trunk of the temporal was cut as it emerged from the disease, and yielded a profuse retrograde hemorrhage.

The operation lasted about an hour, and the patient lost perhaps a pint of blood. In the operation I was assisted by Drs. Vaché, Wilkes, Hosack, and Dykers, and it was performed in the presence of Drs. Barrow, A. Smith, Graham, and Seaman, and about twenty pupils.

After waiting a proper time, to see if any bleeding would occur, and refreshing our patient, although he did not seem exhausted, the wound was closed by several sutures and adhesive straps, and lint, compress, and double-headed roller, completed the dressings.

*Evening.*—Has had a little sleep and feels as well as he expected. No hemorrhage: reaction has come on; took claret and water, with

(Fig. 2.)

toast, which he sat up and ate with a relish, shortly after the operation.

*14th, morning.*—Left two pupils with him during the night, who report that he had slept well, and did not take the morphine that was directed, if he should be restless and in much pain. Pulse 94—skin natural. As he was averse to taking tea or barley-water, from the impression that it would occasion vomiting, he was allowed his favorite drink of weak claret and water.

*Evening.* Has had no evacuation from his bowels; directed the nurse to administer a common enema; pulse 104; skin pleasant; complains of considerable pain in swallowing.

*15th, morning.*—Enema operated favorably. Did not rest well during the night, but in the morning got some refreshing sleep. Skin a little heated; pulse 122.

*Evening.* Says he is more comfortable every way. Skin moist; pulse 108; recommended an enema.

*16th, morning.*—Has had a very undisturbed sleep, and feels better than at any time since the operation. Skin soft; pulse 96. Takes only sugar and water as a drink.

*Evening.* More comfortable than in the morning; has slept considerably during the day. Face more swelled; pulse 100; skin cool and soft; ordered an enema previous to bed-time.

*17th, morning.*—Passed a pretty good night; had a free perspiration. Pulse 98; skin natural.

*Evening.* Feels in all respects better; pulse more frequent than in the morning; skin the same.

18th. Swelling of the face rather diminished; does not complain of any pain in the wound, or in his head; pulse 95.

19th. Some discharge from the lower part of the wound. Dressed it; looks very well. Pulse 88. Ordered chicken water and an enema in the evening.

20th. Says he passed an excellent night, and feels much better. Pulse 96; skin natural; swelling of the face subsiding.

21st. Dressed the wound; discharge very good; pulse 88.

22d and 23d. Dressed the wound; seems improving in all respects.

24th. Removed all the plasters and dressed the entire wound; took away several of the sutures; very much healed by adhesion. Pulse and skin natural; bowels have been moved naturally. Directed more nourishment.

27th. Upon cleansing the wound, ligature from the carotid came away. Removed remaining ligatures and sutures; wound mostly healed; at a small unhealed point, opposite the lobe of the ear, the integuments appear to be taking on the melanotic aspect and a bloody fluid is discharged.

30th. Wound entirely healed, excepting at the point opposite the ear, which has every appearance of a reproduction of the disease. Complains of pain in the left knee, of which he has had several previous attacks. Directed leeches and warm fomentations.

*August 5th.*—Leeches have been repeated, followed by blisters. Pain in the knee less, but tumefaction increased; reunited portion of the wound taking on a melanoid fungous character; a small tumor making its appearance over the right eyebrow. Ordered syrup of sarsaparilla, with a small quantity of mur. hydr. in solution.

12th. Several tumors have made their appearance upon the scalp; fungous of the wound rather increased; a dark spot showing itself in the integuments of the diseased side of the face; tumefaction of the knee increased; complains of pain in the right side. Skin assuming a yellow color.

20th. Tumors all increased in size; hepatic affection very decided; confirmed hectic, and is evidently sinking. Every thing done to make him comfortable.

31st. In all respects worse. Permitted every thing he desires.

*Sept. 5th.*—Died this morning.

After death every exertion was made in order to obtain an examination of the body, but such were the feelings of the friends of the deceased, that even the desire of passing a lancet into one of the tumors on the scalp, with a view of ascertaining their positive character, although I had no doubt of the case being constitutional melanosis, was obstinately refused, and compelled to be abandoned.

On dividing the tumor longitudinally, not a vestige of the original organization of the gland could be observed. The inner surfaces had the appearance of firm tar, and imparted a black color to the fingers when touched. V. MOTT.]

[*Extirpation of the Parotid.*—M. Larrey, in the case of a girl aged nineteen, in whom the chain of lymphatic glands on the left side of the neck became so hypertrophied as to constitute an enormous

tumor in that region, implicating the parotid, (*L'Examineur Médicale*, Aug. 15, 1841,) first effected a resolution of the ganglia by the actual cautery, moxas, mercurial frictions, &c., which treatment occupied two years, and then removed the parotid, when a perfect cure resulted. T.]

## ARTICLE II.—SUBMAXILLARY GLAND.

### § I.

There is *no conclusive proof* to show that the sub-maxillary gland has ever passed into the state of scirrhus or cancer. The examples which have been brought forward for this relate to the conglobate glands which are in its neighborhood, and which are found between them and the border of the jaw and platysma-myoides muscle. Its induration, in consequence of chronic inflammation, in *grenouillette*, for example, is far from being as unfrequent.

Abscesses that become developed in the cellular tissue of its neighborhood, and which remain fistulous after being opened, also produce this result. But however obstinate it may be, this malady ordinarily yields to other means than extirpation, which never seems to be absolutely required. Of the observations which have been published in France, the one which I have made known, and which belongs to M. J. Cloquet, is a pure and perfect example of extirpation of the supra-hyoid ganglions; that of M. Amussat comes probably under the same description, and moreover it is far from being demonstrated that in his patient the operation was absolutely necessary. I would say the same of the case related by M. Warren, (*on Tumors*, &c., p. 129.) It moreover appears to me evident that the tumor of the size of an egg extirpated by M. Sicherer, (*Gaz. Méd.*, 1838, p. 810,) under the title of a maxillary gland, was nothing more than a lymphatic tumor. Was not this the case also with the sub-maxillary cyst removed by M. Malcolmson, and which I have spoken of elsewhere? (see *Salivary Cysts*.) The cases of extirpation of the sub-maxillary and sub-lingual gland mentioned by M. Diday, (*Thèse de Concours*, 1839, p. 59,) being unaccompanied with any detail, are still less conclusive. The tumor of the size of an egg developed under the angle of the jaw in an epileptic, and extirpated by M. Petrunti with much difficulty, the operation causing frightful convulsions for the space of four days, (*Gaz. Méd.*, 1839, p. 122), was, as I conceive, only a lymphatic mass, and not cancerous, as the author supposes. In this case the disease did not repullulate and the epilepsy disappeared. In conclusion, whether the disease be seated in the gland or in the ganglions which surround it, the operation when we have once decided on removing it is nearly the same. The sub-maxillary gland, embraced as it were inferiorly by the concavity of the digastric muscle and separated from the integuments by the facial vein and platysma-myoides muscle, rests superiorly against the inner surface of the jaw, inwardly against the hyoglossus muscle and the mylo-hyoid, upon the external surface of which one of its prolongations extends. The facial artery runs along its upper and inner side. The lingual nerve and the artery of the same name pass below it. Far above, it receives the plexus of the myloid nerve.

§ II.—*Operative Process.*

All that I have said of the form and direction to be given to the incisions, in speaking of the parotid, is equally applicable here. The patient is to have his mouth kept shut, the chin raised up, and the head thrown back and to one side. The gland or tumor is thus fully exposed. In order to reach it, should the semilunar or horizontal incision not appear to answer, the surgeon divides the skin first from above downwards from the border of the jaw as far as to the os hyoides, and afterwards transversely; he then dissects, separates and reverses the flaps thus circumscribed; applies two ligatures upon the facial vein to divide it in the interval, should it interfere too much or cannot be kept out of the way by means of a hook; inserts an erigne into the body of the gland and draws it outwards and upwards, and then backwards and downwards, while he detaches from it, with short cuts of the bistoury, its inferior or anterior half; carefully avoids the lingual artery and its associate nerve; searches posteriorly for the trunk of the external maxillary artery and ties it; brings the erigne forwards and downwards; separates the morbid mass in the direction of the tongue, and then removes it without any difficulty. If we should prefer commencing with a ligature on the maxillary artery, it would be necessary to direct the first incision upon this vessel and to search for it at the point which I have mentioned in another chapter. Nor are we obliged to tie it at all, if we take the precaution to preserve intact up to the end of the operation that part of it at which its branches enter into the gland, and to embrace it as a pedicle by means of a strong ligature. For the dressing and subsequent treatment we proceed in the same manner as after the extirpation of the parotid, bearing in mind, however, that below the jaw union by the first intention has infinitely less danger, and that the totality of the operation is incomparably less formidable than in the sub-auricular notch. I have elsewhere treated in detail of this operation, while speaking of lymphatic sub-maxillary and *supra-hyoid tumors*.

---

## CHAPTER II.

### TUMORS OF THE SUB-HYOID REGION.

#### ARTICLE I.—THE THYROID BODY.

Goitre, or bronchocele, is a tumor which has attracted much attention in the present state of medical science, and which should not be attacked by surgical means until after having unavailingly made use of iodine, *the powder of Sency*, and other pharmaceutical resources which have been much extolled in these latter times; also it is requisite that the tumor should have sufficiently incommoded the patient to jeopardize his life. Serous, sanguineous and purulent cysts.

and vascular, erectile, fungous, aneurismal, tuberculous, calcareous, fibrous, schirrous, colloid, encephaloid, and viscous (gommeuses) tumors, have been confounded with the hypertrophy of the thyroid tissue under the common title of goitre. The surgeon therefore will not be enabled to undertake their cure with advantage until he shall have ascertained their species, or until having consulted the memoir of M. Sacchi (*Arch. Gén. de Méd.*, ser. 11, t. II., p. 246,) on this subject. *Caustics*, employed at the time of Celsus, and since by a small number of practitioners to destroy goitre, are no longer in use at the present day. The steatoma which extended from the superior part of the larynx down to the sternum, and which was cauterized and cured by *Pietsch*, (*Gaz. Salut.*, No. 34, p. 3, 1771,) was it in reality a goitre?

### § I.

*The seton*, which the elder Moreau, according to Burns, which Gérard, and especially Flajani, made trial of or saw employed with success, and which MM. Maunoir and Quadri have extolled as a new resource, is not obnoxious to the same objections. The advantages which may be derived from it have now been indisputably established by a multitude of authentic observations, and wherever, in place of a hypertrophy or fungous or cancerous degenerescence, the tumor shall be found to consist of cysts and liquid, or semi-liquid substances, its application has every thing rational to recommend it. Monro, moreover, is not its inventor. Rogier, (*P. Forest dans Bonnet*, t. III., p. 67,) who speaks of it as in common use, recommends that we should insert two crosswise in place of one; also the rod of red hot iron passed through the tumor as mentioned by Blegny, (*Planque, Biblioth.*, t. V., p. 189, in 4to,) was it not a species of seton? M. Quadri generally inserts it from above downwards, with an instrument similar to Boyer's needle, and for fear of wounding the vessels rarely carries it farther than half an inch deep. However small the mass to be destroyed may be, he introduces two, three, and even four at different points. The goitre soon commences to shrink, and the resolution, which is effected by degrees, continues to go on in most cases, even after having withdrawn the meche, and after the wounds have cicatrized. The thyroid gland is frequently the seat of an indurated enlargement. I have seen those that were schirrous, and Burns and M. Wardrop have found in them encephaloid matter and *fungus hematodes*. But the facts mentioned by the surgeon of Naples, do not prove that the disease may be cured in such cases by the seton. The three cases which are related by M. O'Beirn, (*Arch. Gén. de Méd.*, 2nd ser., t. VI., p. 415,) are not very conclusive. M. Nick, (*Gaz. Méd.*, 1835, p. 311,) who approves of it, and who alleges that by means of the seton M. Klein has succeeded in six cases out of seven; and M. C. Hutchinson in two out of three cases, and M. Hauslentner also in two cases; has not been enabled to avert the censures which have been cast upon this method by Sommerville and Kennedy, (*Gaz. Méd.*, 1837, p. 311.) It was with cysts that M. Addison (*Ibid.*, 1837, p. 25,) obtained the three successful results that he mentions, and the case cited by M. Vado, (*Thèse*, No. 123, Paris, 1832,) also does not relate to a tumor of a

bad character. In severe cases it has been proposed to apply the ligature upon the bronchocele, to extirpate it or to ligate the principal arteries which enter into it.

## § II.—*Ligature.*

It is to Moreau, surgeon of the Hotel Dieu, that Valentin ascribes the suggestion of attacking goitre by the ligature. One of the patients thus treated in 1779 was not cured, but the other recovered perfectly. The tumor in the first was a cancer, that of the second was of a fatty nature. The surgeon inserted a double ligature through its base, as if for the purpose of dividing it into two equal parts, which he afterwards strangulated separately. Some years subsequently, viz., in 1791, Desault also had recourse to it, but it was for the purpose of terminating an extirpation, the last stage of which was attended with too much danger. Brunninghausen used it with entire success in 1805, to destroy an enlargement of the size of an egg, which was situated at the fore part of the neck, between the larynx and sternum, in a young man 25 years of age.

A child 12 years of age, operated upon by M. Mayor in 1821, for a goitre of the size of an orange, was discharged from his hospital perfectly cured at the expiration of a month. In a young man 21 years of age, the tumor occupied the front part and both sides of the neck, and extended from the angles of the jaw and the parotid region, as far down as to the sternum and clavicles. Of the three lobes of which it was composed, one, or that of the middle, equalled in volume the head of a 7 or 8 months' fœtus. The entire mass below the jaw was nine inches in height and 26 in breadth. The general condition of the patient was bad, but M. Mayor nevertheless effected a radical cure in less than two months! Nor was he less successful in a lady of Sackendorf, who had in vain consulted the most distinguished medical men of all countries for the removal of a tumor, which she had had for the space of about thirty years. This tumor, which continued to increase, occupied the entire left side of the neck, had pushed the larynx to the right, and appeared seriously to compromise the life of the patient. His process consists in laying bare the anterior surface of the bronchocele, in afterwards isolating it from the subjacent parts by means of the fingers or the handle of the scalpel, and then applying a strong ligature upon the root of each of its lobes, or traversing its base with a double ligature, which admits of its being strangulated above and below. In place of one or two ligatures he sometimes employs as many as four, each one of which is then made to include a fourth or third of the gland, and as may be supposed, the chaplet constrictor is the one to which he accords the preference. From these details, nevertheless, it is evident that the ligature here is but an auxiliary means, or a resource against hemorrhage, when we are fearful of wounding some vessels of importance; and that if we were sure of avoiding all the large arteries with the bistoury, extirpation would be still far preferable. It is an operation, moreover, which is not unattended with danger; and two of the patients operated upon by M. Mayor himself, perished. It causes suffocation, extreme anguish and difficulty of respiration, and frequently

some of the symptoms of typhoid fever. The soldier of M. Malle, (*Thèse de Concours*, Strasbourg, 1836, p. 27.) created the greatest degree of alarm in the mind of the operator. Consequently I should not recommend it, except the tumor is first detached by means of the cutting instrument or fingers to as great an extent as is possible, in order that there may be a pedicle only instead of a large base to be strangulated, and upon the condition also that the goitre should be promptly excised, external to the ligature, and not left to putrefy in the wound.

### § III.—*Obliteration of the Arteries.*

Some practitioners have supposed that by tying the thyroid arteries we might probably obtain the resolution of the goitre. Burns ascribes the first suggestion of this practice to W. Blizard. The patient operated upon by this surgeon did very well during the space of a week; but repeated hemorrhages and hospital gangrene, which soon exhausted him, ultimately caused his death. Since that period, viz., in 1814, M. Walther, who adopted the precept of the English surgeon, performed the operation with entire success. The same is to be said also of M. Carlisle, and we are indebted to M. H. Coates for another successful result. M. Earle, M. Green, and M. Chelius, have been no less fortunate; and M. Boileau being compelled in 1825 to tie the carotid for a traumatic lesion, had the satisfaction not only to save his patient but also to cure him of a goitre, which had troubled him for a long series of years. M. S. Cooper, however, informs us that a ligature upon the thyroid vessels, as performed by M. Brodie, produced no diminution in the volume of the tumor. It is necessary also to add that M. Langenbeck, having been obliged to tie the two carotids after having tied the right superior thyroid artery nine days before, saw his patient die on the following day. These facts, though not very numerous, are nevertheless sufficient to induce us to submit a remedy of this kind to new trials. We ought especially to attempt it in pure and simple bronchocele or hypertrophy of the thyroid body, and in all cases where the vascular system predominates in the tumor. Instead of one or two, we should in my opinion tie the four thyroid arteries; otherwise it is to be feared that the blood which is arrested upon one side, may come out again from the other. The operation after all, has nothing in it formidable to the skilful surgeon. If the natural pulsations of the vessels which are to be laid bare are not sufficiently strong to serve as a guide for the instrument, we must proceed to seek for each thyroid artery, where they are given off from the carotid for the upper ones, and on the inner border of this trunk for the lower, following out in other respects the rules elsewhere laid down.

### § IV.—*Injections.*

If there should be a cyst, whether serous or sanguineous, irritating injections, as recommended by Rullier and others, might have some chance of success. I would not recommend them to be made with chlorine, as has been suggested by M. Decondé, (*Encyclog. des Sc.*

*Mécl.*, 1836, p. 6,) but I would willingly make use of the solution of the tincture of iodine, in the same way as for any other cyst.

### § V.—*Incisions.*

Having noticed that an enormous purulent goitre which contained calcareous concretions, and mention of which is made by Sellié, (Rougemont, *Bibl. du Nord.*, p. 134,) was cured by making an incision into its tumor; that M. Beck (*Arch. Gén. de Méd.*, 3e sér., t. I., p. 319,) had succeeded in two out of three cases, by excising a part of the cyst; and that a thyroid cyst, which had suppurated, was also cured by incision in the case of M. Rey, (*Thèse*, No. 79, Paris, 1834,) and in that of M. Laugier, (*Dict. de Méd.*, 2d edit., t. IX., p. 180;) I have established a method (*Bull. de Therap.*, t. XI., p. 344,) which still better secures the success which has been obtained, by means of four incisions on as many different thyroid cysts, by M. Petrali, (*L'Experience*, t. II., p. 173.) I incise the tumor on four or six points of it, according to its volume, giving to each incision an inch in length. By means of the finger, here introduced, I empty and cleanse the cyst; I then pass into these wounds a meche of ravelled linen, which is to be moved in the manner of a seton during the space of four or five days, until the suppuration has been perfectly established; I then withdraw them, and the tumor from this time is treated as an abscess. Three patients have been operated upon by me in this manner at the hospital of La Charité, and another in private practice. The disease in the three cases was an enormous purulent goitre; two of these were cured in six weeks, and one died; the fourth case had a sanguineous cyst with thick walls, and recovered. Incision of *thyroid tumors or cysts* also is far from being always exempt from danger. M. Bégin, (*Elem. de Chirurg.*, 2d edit., p. 23,) being desirous of incising a tumor of this description, which rested upon the trachea, cut down upon a vascular areolar mass, the extirpation of which was impossible, and the incision into which, which had already caused repeated bleedings, might have been followed by a fatal hemorrhage. The operation was not completed, and the patient recovered, but retained his tumor.

### § VI.—*Extirpation.*

By means of extirpation we remove the totality of the disease, and the patient is promptly relieved of it; but it is attended with so many and such formidable dangers, that the great majority of authors, at the present time, agree in proscribing it.

A. That, at the time of Albucasis, a patient who was submitted to this operation should have died of hemorrhage, has nothing in it very surprising; that the young lady mentioned by Palfin succumbed during the operation from the same cause, we may also readily conceive; though one of the patients cited by Gooch perished, exhausted at the end of eight days, and that in order to save the other it became necessary that the assistants should relieve each other during the space of a week, in order to compress without intermission, by means of their fingers, all the arterial branches which had been

opened; though an officer, whose history is given by Percy, also perished from hemorrhage, and that the patient operated upon by Dupuytren survived the ablation of the tumor but thirty-five hours; though the instances of extirpation of goitre adduced by Freytag, Theden, Desault, Giraudi, Fodéré, and the barber who, according to Paradi, performed it successfully upon his wife, may not all of them be very satisfactory; and though the young girl treated by Klein, (*Graefe und Walther's Journ.*, vol. I., p. 120,) was seized with an apoplectic fit and perished from it,—we should nevertheless be wrong in censuring, in absolute terms, the essays made to render us more familiar with this operation. Peckel and Ravaton (*Pétrequin, Bull. de Ther.*, t. XI., p. 344,) have performed it several times with success, and Vogel (*Bibl. Chir. du Nord.*, p. 391,) has been no less fortunate. M. Graefe, (*Gaz. Méd.*, 1835, p. 169,—*Rufz, Arch. Gén. de Méd.*, 2e sér., t. X., pp. 25, 41,—*Graefe und Walther's Journ.*, 1820,) who lost one of his patients, has cured two others. M. Green (*Lancet*, 1829, vol. II., p. 351,) succeeded in extirpating one of the lobes of the gland, and M. Warren, (*On Tumors, &c.*, p. 305,) who tied the carotid, also saved his patient. That of M. Roux (*Rufz, Arch. Gén. de Méd.*, 2e sér., t. X., pp. 25, 41,) died after the expiration of a few days; but that of M. Voisin (*Gaz. Méd.*, 1836, p. 372,) recovered perfectly.

The enormous tumor extirpated by M. G. Bell, (*Arch. Gén. de Méd.*, t. IX, p. 283,) soon repullulated. But the cyst removed by M. Gubian (*Ibid.*, t. XII., p. 315,) did not reappear. By combining extirpation with the ligature, as has been done by M. Mayor and M. Hédénus, (*Graefe und Walther's Journ.*, vol. II., p. 240,) there can be no doubt that in future some successes might be obtained from it. The most complicated cases could not intimidate this last mentioned surgeon, who in 1822 could already enumerate six successful results obtained by him. His process differs from that of M. Mayor in this, that he carefully dissects the bronchocele down to its deep-seated surface, and ties the arteries in proportion as they are divided by the instrument; and in this also, that with him the ligature, which he applies in other respects after the manner of the practitioner of Lausanne, but which he knots in the same manner as for obliterating a large vessel, has no other object than to strangulate what he dare not venture to divide, and to enable him to excise the entire morbid mass immediately, with security. For myself, however, I should not decide upon extirpation of an actual goitre, until after having satisfied myself that there was not any co-existing lesion of the heart or tendency to apoplexy, and that the surrounding lymphatic glands were sound; and until after having made trial of either the seton in the manner of M. Quadri, the simple incision indicated by Fodéré, and employed successfully by Delpech, or the numerous incisions which I have recommended, or as Rullier advises, an irritating injection into the cyst, if any exists, or the previous ligature upon the thyroid arteries; and not until after the pressing entreaties of the patient, and only in cases where the bronchocele instead of constituting only a simple deformity, forms a disease whose progress and character threaten the life of the individual.

**B. Operative Process.**—We will suppose that there exists a goitre

which involves every portion of the gland. The preparations are very nearly the same as for the removal of the parotid. The patient is placed upon his back, with the head gently reversed, and supported by assistants. The operator being situated on the right side, makes upon the median line a first incision, which commences above, and is to finish a little below the tumor; transforms this wound into a crucial incision; detaches the flaps, and dissects them down to their base; divides transversely the fleshy fibres which he cannot push aside, reverses them towards their attachment if they are sound, or comprises them in the subsequent excisions if they are diseased; ties such vessels as interfere with him; reaches by degrees the borders of the tumor, which he draws towards him while tearing rather than cutting it out, and finds deep down, at their superior and inferior part, the four principal arteries of the organ, each of which he isolates and surrounds with a ligature. Avoiding with care the trunk of the carotids, the internal jugular, the descending branch of the great hypoglossal nerve, the pneumo-gastric, and the great sympathetic and the cardiac nerves, which are seen a little farther to the outside, crossed by quite a considerable number of secondary veins, the surgeon then detaches the tumor at its upper part, from the sides and anterior face of the larynx, from which it is separated only by the thyro-hyoid muscles, cellular lamellæ, and some small arteries which must be tied, and which come from the lingual or maxillary branches. Returning towards its borders, which he raises and separates from the œsophagus or trachea, near which run the laryngeal nerves, he recognizes when the tumor holds no longer, except by its lower border, whether the venus plexus which issues from it, and the thyroid artery of Neubauer, which very frequently enters into it, would make its complete separation dangerous. If so he includes all these objects with a ligature, or traverses their pedicle with a double ligature, and strangulates them as powerfully, and as near to their root as possible, after which he may excise without any fear the totality of the goitre. So laborious and delicate a dissection cannot be rapid. The patient requires to be allowed to repose from time to time, in order to breathe. All kind of pressure upon the trachea or larynx should be carefully avoided, and the surgeon should vigilantly bear in mind that if the inspirations are not free, the blood will be instantly seen to accumulate in the veins, and to rush out in large quantities from the slightest cut of the bistoury.

Before proceeding to the dressing, it is important that even the smallest arteries should be tied or twisted. As to the veins, they will cease bleeding as soon as the patient shall be free from oppression and be enabled to dilate his chest freely and without fear. Should it be otherwise, the ligature must be applied to them. The convulsive movements and even death which have sometimes supervened, during the extirpation of tumors connected with a great development of the vascular system, might be attributed in this region to the introduction of air into the veins, (see Volume I. ;) M. Boullay, (*Gaz. Méd.*, 1839, p. 79,) who saw a horse perish a few minutes after bleeding the jugular for an attack of pneumonia, ascertained that the air had been introduced in large quantity into the heart and vessels; but as I have already said, it remains for the fact

to be demonstrated in all the cases of this kind which have been related. The surfaces being thoroughly sponged and the ligatures brought to the angles of the solution of continuity, nothing more remains to be done than to approximate the flaps of the wound and to close it up more or less perfectly. As in front of the neck the centre of the division is more elevated than the sides, it cannot but be attended with advantage in undertaking immediate reunion, either by means of adhesive plasters or even a few points of suture, provided however that with the exception of a few ligatures we are not forced to leave any foreign body under the skin. The different portions of dressing moreover should be light and gently applied. All compression in such a region would be dangerous, and too great a number of pieces of dressing would cause an injurious accumulation of heat. Should the tumor involve only one side of the thyroid, or if independent of this gland this tumor should be on another point of the anterior half of the neck, the modifications which would require to be made in the process which I have described are too unimportant and too easily anticipated to make it necessary to point them out in detail.

#### ARTICLE IV.—TUMORS FOREIGN TO THE THYROID BODY.

Synovial cysts, loupes and lymphatic tumors, &c., may develop themselves in the neck as well as in any other region; but having treated of these in another chapter, it is not my intention to notice them again in this place. I have successfully removed an atheromatous cyst of the size of a large nut, which was situated in the supra-sternal fossa of a young American, between the layers of the fascia cervicalis; I have seen lymphatic masses and aneurismal tumors of the aorta elevate themselves from behind the sternum as high up as to the neighborhood of the larynx; but it has not fallen to my lot to effect the extirpation of a degenerate thymus, an operation mentioned by M. Haugster, (*Arch. Gén. de Méd.*, 2nd ser., t. III., pp. 109, 263.) There is still another sort of tumor of the neck, viz: the emphysematous, upon which I have only one word to say. This tumor, in the case of M. Ollivier, (*Ibid.*, t. I., p. 421,) which followed a sudden crepitation, was situated on the supra-sternal region; in the cases of the English physician, (*Med. and Phys. Journ.*, June, 1833,) when irritated by exertions it extended itself rather towards the face, and in the case of M. Malle, (*Thèse de Concours*, Strasbourg, 1836,) or M. Bégin, (*Elem. de Chirurg.*, &c., 2nd edit., t. II., p. 24,) it was occasioned by the extirpation of a thyroid tumor. It is a description of tumor which is imputable to some laceration in the air passages, and which must be treated like any other emphysematous tumor

## CHAPTER III.

## AIR PASSAGES.

## ARTICLE I.—BRONCHOTOMY.

Under the name of *bronchotomy*, it is my intention to speak of the artificial and methodical opening of the air passage in its cervical region, and not in that of the bronchi, as its etymology would lead one to suppose. At the present day, when it is performed on various points of the respiratory tube, the word *bronchotomy* ought to be applied to the operation in general, while in its special applications it would comprehend *tracheotomy*, *laryngotomy* and *laryngo-tracheotomy*. Asclepiades is the first, I believe, who ventured to perform it. No one before Antylus and Paul of Egina, had described it. C. Aurelianus, Aretæus and most of the Greek authors repel the very mention of it; and Rhazes advises it only in cases threatening immediate death. Though Albucasis, in order to prove that the divided cartilages will reunite, cites a young girl who had cut her throat and who perfectly recovered; that Avenzoar made with the same object some successful experiments upon goats, it is not until we arrive to the year 1543, that we find this operation again revived by M. Brassavole. It is only since the time of F. ab Aquapendente, that all writers have admitted its utility, and even its necessity under certain circumstances. It is far from being the fact, however, that opinions have always been unanimous upon the cases which required it.

§ I.—*Indications and Appreciation.*

A. P. d'Abano, who calls it *subscannation*, and after him Gherli of Modena, G. Martine, &c., consider bronchotomy indicated in all cases of tonsillary or laryngeal *angina*, which threaten the suffocation of the patient; but, though advocated by Mead and Louis, their opinion, which goes back moreover as far as to the time of Avicenna, and which has been zealously opposed by Cheyne, is at the present day scarcely sanctioned except by Baillie and Fare. Anginas that are purely inflammatory, however intense they may be, rarely make it necessary to have recourse to a remedy of this kind. It would be difficult to comprehend why an acute engorgement of the tonsils, for which Flajani ventured to have recourse to it, should ever require it, unless it were impossible to open into the mouth and to penetrate down to the pharynx. The same may be said with greater reason of their chronic enlargement, which is relieved by excision with much less danger. When *the tongue becomes swollen* suddenly, in such manner as to fill up the mouth and close the arches of the palate, Richter and B. Bell, who recommend bronchotomy, had without doubt forgotten that in such cases two or three deep incisions upon the dorsum of the diseased organ will effect its diminution, and very probably were unaware of the observations of De La Malle on this subject. It would be difficult also for me to believe that it might

not have been possible to dispense with it in the case where M. Burgess performed it, since in that case there was nothing but an inflammatory intumescence, produced by a burn at the bottom of the buccal cavity. On the other hand it is almost universally admitted since the time of Desault, that it is not applicable to cases of submersion, and that Detharding, in prescribing it as a remedy in asphyxia from drowning, entirely misconceived the manner in which death takes place under such circumstances. Nevertheless, M. S. Cooper, who considers it more prompt and easy than the introduction of a gum-elastic catheter through the nose or mouth, justly argues, as it appears to me, that it should not then be proscribed without restrictions. Should the mouth be firmly closed, and it became impossible for the catheter to be inserted into the entrance of the larynx, bronchotomy would be better than nothing when it was important to act speedily and to force the air to pass into the lungs. When we reflect upon the difficulty of shutting up the glottis completely, by means of the tube which we insert into it, and of preventing the air, which is blown in, from escaping into the digestive passages, in all those cases in which the surgeon deems it proper to attempt artificial respiration, we cannot but be induced to accord to it a preference over simple catheterism.

B. *Œdematous Angina*, that is to say, a serous engorgement of the lips of the glottis, is still another disease for which bronchotomy appears to constitute the remedy par excellence. In sustaining the respiration, it gives the physician time to attack the disease by suitable remedies, and to the organism the means of subduing it, or at least of making farther resistance to it. The antagonists of Bayle, who was the first who mentioned it for such cases, reject it under a pretext which does not appear to me valid. Their permanent canula by the natural passages could not certainly remain without danger in the trachea during the space of from eight to fifteen days; while a canula which has been once inserted through the artificial opening into the respiratory tube, occasions very little inconvenience to the patient. I am of opinion, therefore, with M. Lawrence, that in this description of disease, which moreover is almost constantly fatal, it deserves some attention, and that it would offer infinitely better chances of success than scarifications of the infiltrated parts, as proposed by some practitioners.

The patient whom M. Roulois, of Mayenne, mentions in his thesis, and who was operated upon at the Hospital of St. Antoine in 1828, by M. Kapeler, died it is true at the expiration of thirty-six hours, but after having been restored as it were by a miracle from death to life, and dying very probably because the air could not be made to pass in sufficiently large quantity and uninterruptedly into the lungs. The case mentioned in the *Journal Complimentaire* was less unfortunate, inasmuch as he survived. A woman operated upon by M. Purdon, (*Arch. Gén. de Méd.*, 2e sér., t. II., p. 102,) also recovered. M. C. Broussais, (Coqueret, *Thèse*, No. 185, Paris, 1834,) was no less fortunate. Operating for a thickening of the mucous membrane of the larynx, M. Regnoli, (*Revue Méd.*, 1829, t. II., p. 520,) succeeded in two instances, and M. Senn once. M. Fournet has published two other *successful* cases. M. A. Robert has also communicated to me

two others which belong to him. I have performed tracheotomy but twice as a remedy in œdematous angina, and both patients were cured. We should be wrong then not to have recourse to it under such circumstances.

C. *Tumors and engorgements in the vicinity.*—A polypus, or any tumor whatever in the nasal fossæ or pharynx, the thyroid body, or certain lymphatic ganglions, any of which have become swollen or so hard and voluminous as to prevent the air from passing into the trachea, do not render the operation indispensable, only so far as there may be imminent peril of suffocation, or if it shall have been found impossible or attended with too much danger to attempt the ablation of these morbid masses. It was, chiefly, for these cases only that Sharp reserved it; for it did not appear to him to be absolutely required in the extraction of foreign bodies. It might, moreover, be advantageously performed if, in consequence of a wound or otherwise, the larynx had become completely obliterated, as in the young man whose history has been given by M. Reynaud, (*Journ. Hebdom. Univers.*, t. III., p. 201.) M. Porter, (*Gaz. Méd.*, 1838, p. 392.) employed it with success in a case of gangrene of the epiglottis and hyoid region caused by suicide. M. Warren, who undertook to perform it in a patient in order to remedy the *entrance of air into the veins*; and M. Sampson, (*Ibid.*, 1837, p. 667,) who found nothing so advantageous to restore a *drunken man*, might both, however, in my opinion, have dispensed with it.

D. *Foreign Bodies.*—It is for the purpose of reaching heterogeneous substances which sometimes become introduced into the larynx or trachea, that the operation of bronchotomy, since the time of F. Monavius, has been most frequently performed. It has been made use of and might be employed in this manner, in order to extract clots of blood that have come from the mouth, or even from a wound in the larynx, lumbrici worms, a leech (Lacretelle), flies, portions of food, (Thierry, *Bibl. Méd.*, 1829, t. II., p. 450,) such as small fish bones, (Willaume, *Bull. de Fér.*, t. XXIV., p. 167,) fowl, pieces of mushrooms, apples, chesnuts, acorns, of polypus in the pharynx, a cherry pit, a prune, apricot, harrico bean, raisin-seed, melon-seed, (Jameson, *Bull. de Fér.*, t. I.,) a pill, a filbert, a coin of gold, piece of silver, locks of wool or tow, a ball, a marble of the diameter of 8 lines, (*Arch. Gén. de Méd.*, 2e sér., t. II., p. 125,) a button mould, a pebble, pin, needle, (Blandin, *Bibl. Méd.*, 1829, t. II., p. 450,) fibrous tumors, probably syphilitic (*Arch. Gén. de Méd.*, t. V., p. 564,) polypi (Swinger, Morgagni, Lieutaud, Herbiniaux, Desault, Voigtel, Windt, Otto, Prinz, Albers, R. Gérardin, &c.) and hydatids (Aubertin, Delonnes, and Harless;) encysted tumors (Albert,) fungous or sarcomatous tumors (Tortual,) lymphatic and warty tumors (Wurtzer,) schirrhous and cartilaginous tumors (MacIlvaine in Urner, 1833, *Obs. Méd.*, 1835, p. 116), developed in the interior of the larynx; a piece of cartilage, tendon, wood, iron, or membranous concretion; in a word, for the extraction of all bodies whatever, that may become lodged in the glottis or trachea. As soon as the presence of one of these objects in the respiratory passages is clearly established, we are justified, unless we can reach it better through the mouth by means of the fingers or forceps, in calling to our aid the resources of

bronchotomy. The sound of a small stone moving up and down, and which M. MacNamara mentions, (*Dub. Hosp. Reports*, vol. V., p. 592,) after having performed bronchotomy successfully in such cases in two instances, is a very good sign. In the case published by M. D'Arcy, the bean, though the accident had happened only a few hours before, had become swollen to treble its size. Though the first symptoms which these substances have produced may partially subside, it nevertheless will continue to be clearly indicated. In fact the monk who is mentioned in the *Eph. des Cur. de la Nat.*, and who was afraid at first to complain, died of phthisis, but not until after the expiration of two years.

One of the patients mentioned by Louis appeared so well that he was considered almost as cured, when he died near the expiration of the third week. Another, who lived several years with a Louis d'or in the bronchi, nevertheless ultimately died. Tulpus. V. D. Wiel, Bartholin, Pelletan and Dupuytren have also seen in certain cases the foreign body admit the respiration to reacquire, in some sort, its natural function, and not cause death until after one or more months, or even years. There are cases also in which, after the lapse of this space of time, the bodies have been expelled spontaneously; as for example, the chicken-bone mentioned by Sue. A lead pencil, an inch and a half long, was thus ejected after the lapse of six years, (Gridley, *Journ. des Prog.*, t. XIII., p. 269.) M. Guastamahia (*Gaz. Méd.*, 1838, p. 797,) mentions the case of a cherry-nut which was thrown out in a paroxysm of coughing, after having remained two months and a half in the trachea. Monteggia mentions a similar case of a tooth swallowed by a young lady. But these fortunate efforts of the system so rarely take place, that it would be imprudent to count upon them, or ever to dispense with bronchotomy under such idle pretexts.

E. *Foreign bodies lodged in the œsophagus*, and the inflammatory engorgement which wounds and injuries of the neck sometimes produce, have also induced some physicians to resort to bronchotomy in order to prevent suffocation and give time to attack the principal disease. *Habicot* performed it upon the spot upon a boy who, returning from the fair, found no better means of escaping from robbers than to swallow, inclosed in a packet, the pieces of gold which he had in his possession. He performed it in the same manner successfully in a patient who being severely wounded, was upon the point of perishing from inability to respire. This is the way in which we undoubtedly ought to act, should life be seriously menaced by the presence of foreign bodies in the œsophagus, or by an intumescence in the lips of a wound in the larynx, provided it should be impracticable to remove by any other mode and instantaneously the cause of the suffocation. A student of medicine, from suffering pain in the pharynx, supposed that he had swallowed a bone while eating soup. According to his account, this bone consisted only of a very small fragment. The exploration of the throat led to no discovery. The accidents which were at first quite serious, subsided by degrees; but about the twentieth day this young man was seized with suffocation, and vomited and threw up a corroded bone of the size of a nut. Bronchotomy, which nevertheless became necessary, was performed

by M. Sanson, and the general health of M. F. was gradually re-established.

F. *Croup*, or laryngeal and tracheal *diphtheritis*, that formidable malady, the nature of which has been no less clearly elucidated than its treatment by the admirable researches of M. Bretonneau, is one of those affections in which it would at first sight appear that bronchotomy might be resorted to with the greatest degree of advantage. Nevertheless, in spite of the assertions of M. A. Severin and Bartholin, and of some other practitioners of the seventeenth and eighteenth centuries, who assert that they had in many instances had recourse to it with successful results, the physicians of our epochs still doubted in 1825, if in a disease of this description it can be of any great value, or that there existed in science a single conclusive or well authenticated example of cure which could in reality be attributed to it. Those which are cited by M. S. Cooper, whether in his own name or in that of M. Lawrence, or of M. Chevallier, do not prove in fact that the cases treated by these physicians was legitimate croup. The case related in the name of Andree by Bursieri, Locatelli, Michaelis and White, is the only one which is accompanied with details sufficiently circumstantial to afford any satisfaction upon this point. The light in which bronchotomy has hitherto been considered would not enable us to derive any very great advantage from it in croup. We cannot, in fact, understand how it could remedy the inflammation or spasm of the larynx, which, according to Royer-Collard, &c., ultimately cause death in this disease; or the pulmonary engorgement, any more than it can the reproduction of the morbid product. In this point of view M. Caron has certainly exaggerated its importance, while MM. Desruelles, Bland, &c., have very properly contested its utility. But it is not in this way that it should be considered. Patients attacked with croup die from want of the ability to respire. This asphyxia, which is caused by a false membrane or the engorgement of the laryngeal membrane, does not depend on spasmodic lesions, which are rendered impossible or insignificant in the larger bronchi, the trachea and the larynx, by their cartilaginous texture. It is less with a view of extracting the membraniform concretions that we have recourse to bronchotomy in this disease, than for gaining time and placing the patient in a condition to breathe while we are devising the means for his cure.

M. Bretonneau has shown that when the trachea is once opened, we may introduce into it advantageously a solution of calomel, or even one of nitrate of silver, and follow up the false membrane as far as into the bronchi. Under this point of view, bronchotomy is a precious resource, which should be made use of wherever the disease, having reached into the larynx or below it, can no longer be attacked through the mouth by means of topical applications, and where, notwithstanding it has not yet passed beyond the first bronchial divisions. Unhoped for successes have come to the support of this doctrine. In the month of July, 1825, M. Bretonneau, being called to see Mlle. de Puységur, four years of age, whose three brothers had already perished from croup, and who herself was laboring under it to a violent degree, freely laid open the trachea; placed a canula in the wound; saw the false membranes escaping from it in great quantity

during the space of several days; blew in calomel in powder, which was badly supported, subsequently the same substance diluted in water, and thus succeeded in saving this afflicted child. In a boy 7 to 8 years of age, and whom I had an opportunity of examining at Tours, in 1827, a month after his cure, and who in the most advanced stage of the disease had been abandoned as upon the point of expiring by his parents, M. Bretonneau laid open the trachea as in the preceding case; saw life returning at the expiration of a few minutes; effected the extraction of numerous membraniform concretions; and found himself under the necessity a short time after of introducing through the canula which he kept permanently in the wound, a solution of nitrate of silver as far down as into the bronchi, when, after various obstacles which were destroyed as soon as they made their appearance, the child was entirely restored. In October, 1831, the same practitioner was no less fortunate in a third patient. The child, which was 11 years of age, was considered as dead, when M. Bretonneau was sent for to him. He instantly opened the trachea, and after various accidents which were overcome by the most judicious treatment, this young patient was finally completely restored. Similar successes have been since obtained by M. Scoutetten (Coqueret, *Thèse*, No. 185, Paris, 1834,) M. Gendron (*Journ. de Conn. Med. Chir.*, t. I. et. II.,) of Chateau du Loir, and by M. Gendron (*Acad. Roy. de Med.*, 1838, t. III., p. 391,) of Vendôme, M. Gerdy, (Chrestien, *Arch. Gén. de Méd.*, 2nd ser., t. V., p. 517,) M. Crozat (*Precis Med. d'Indre et Loire*, 1833, p. 5,) and especially by M. Trousseau, (*Journ. des Conn. Med. Chir.*, t. I. II., and III.) Out of 18 or 20 operations, M. Bretonneau at the present day counts five or six cures. Out of 60 cases and over, M. Trousseau points out more than 20 successful results. I must however remark, that I lost the four children upon whom I performed it, and that up to the present time, it has been unavailingly made trial of in a great number of patients at the Hospital des Enfants. It has been decided upon too late, as has been remarked by M. Maingault, (*Arch. Gén. de Méd.*, t. XXX., p. 419; 2nd ser., t. I., p. 129,) and the consecutive treatment requires too many precautions to allow of its succeeding with every one as well as it did with MM. Bretonneau and Trousseau.

G. There are also other diseases which it would appear to me might be advantageously treated by bronchotomy. *Laryngeal phthisis*, for example, and chronic phlegmasias, which ultimately result in producing a degree of *contraction in the glottis*, as in the case cited by M. Gintrac, (*Revue Méd.*, 1830, t. I., p. 106.) The air finding a free passage below the disease, would leave the larynx in repose, and would no longer interfere with the salutary efforts of the system. Moreover, we should thus be enabled to place through the new opening, should it become necessary, topical applications immediately in contact with the diseased part. Trials of this kind have been made since being recommended by me; a pregnant woman affected with a syphylitic ulcer in the larynx, and upon the point of suffocating, was cured in this manner by M. Purdon, (*Arch. Gén. de Méd.*, 2nd ser., t. II., p. 102.) A man who had ulcers of the same character, accompanied with engorgement of the cordæ vocales, and whom I operated upon at the Hospital of La Charité, in the month of No-

vember, 1838, was also restored. M. Trousseau and M. Amussat, by operating in this manner in cases of tubercular phthisis, have prolonged at least the lives of some of their patients.

H. Horses affected with *cornage* also have the glottis contracted, and present to the observer experiments, all of which are at hand, in favor of what I have just advanced. Two of these animals employed in a manufactory of minium at Tours, recovered their ordinary condition of health after having had a large canula fastened into their trachea. M. Barthélemy (*Bull. de la Fac. de Méd.*, t. VII., p. 27,) and other veterinary practitioners, have cited cases that are nearly similar. Applied to man, these facts have not deceived the expectation of practitioners. M. Clouet, of Verdun, (*Journ. de Prog.*, t. XVII., p. 226,) caused a similar canula to be worn for the space of twelve years, by a woman whom a fistula in the larynx, and other wounds, had exposed to the risk of suffocation. Price imputed ten years of flourishing health to a remedy of this description. M. Bulliard, in 1824, restored to health a young soldier whom a chronic laryngitis, and not croup as he supposes, had brought to the verge of death after many paroxysms of suffocation, by placing in his larynx a canula, which the patient wore during fifteen months. M. Godève was no less fortunate, in 1825, in another patient, affected, he says, with an ulcer in the larynx, but rather, as I think, with an engorgement of the cordæ vocales, and who was enabled to remove his canula without any inconvenience at the expiration of six months. The patient of M. White carried it for the space of two years, and that of M. Senn eleven months. The same occurred nearly in the two patients operated upon by M. Regnoli.

I. *Recapitulation.*—In conclusion, bronchotomy is an operation to be made trial of in all cases, or nearly in all cases, where a mechanical obstruction from whatever source it may arise, has a tendency to produce asphyxia. M. Gendron, (*Journ. Hebdom.*, 1836, t. I., p. 380,) who has seen two cases, proposes even that should a fistula exist between the trachea and œsophagus, bronchotomy should be had recourse to in order to cauterize the fistula through his bivalve canula. The operation, in reality, has but little danger connected with it. If up to the present time it has not been more frequently performed, it is from its effects, except in cases of foreign bodies, not having been accurately understood; from its having been supposed, that in order to re-establish respiration it was sufficient to open any passage whatever for the air; and from not having reflected that if the artificial opening is perceptibly less in extent than the natural passages, the lungs remain incapable of completely performing their functions, and that, in such cases, the design of the operation is to a great extent defeated. This is a truth which, placed beyond all dispute by M. Bretonneau, I consider that I have established, and the practical consequences of which ought to be of the most beneficial character. In one of the horses just mentioned the tracheal canula was only six lines in diameter. As soon as the animal became fatigued, he was seen gasping and out of breath. A large canula an inch in diameter was substituted for the first, and the horse immediately breathed freely and could undergo the most violent exercise. In the little patients who were cured by the practitioner of Tours by

means of bronchotomy, was not the canula naturally too small, or made so by the concretions and mucosities which contracted its diameter? Though the symptoms of asphyxia momentarily disappeared, they were found speedily to return. But on the contrary, it was no sooner cleared out, or a larger canula made use of, than the child seemed to revive. The same effects were observed in the cases of MM. Bulliard, Senn and Trousseau, and I was enabled to demonstrate, on my part, to a great number of persons, the correctness of this observation in regard to the patients whom I operated upon at the Hospital of La Charité in 1837 and 1838. W. Cullen, (*Journ. de Prog.*, t. VII., p. 144,) who neglects to give credit for this suggestion to M. Bretonneau, collected, in 1827, other facts not less conclusive, in order to sustain it and to give currency to it in England. After all, every one may, on this point, experiment on himself. Should we, for example, diminish the volume of the column of atmospheric air which is naturally inspired into the lungs, or diminish the openings of the nostrils one-half or two-thirds of their dimensions, by closing them upon a portion of quill or gum-elastic catheter, and keeping the mouth shut; the respiration will not be arrested, but it will soon become painful, and so much the more so in proportion as the passage for the air shall be more contracted. It is important then, when we venture to have recourse to bronchotomy, with the view of sustaining an artificial respiration beyond the space of a few minutes, that we should open largely into the respiratory tube, and that we should leave in the wound a canula also of very large diameter.

## § II.—*Examination of the Methods.*

This leads us to examine which ought to have the preference, tracheotomy, laryngotomy, or laryngo-tracheotomy. The ancients had no occasion to discuss this question, as they attempted only the opening of the trachea. The opening into the crico-thyroid membrane, has only been employed in practice since the time of Vicq-d'Azyr, who proposed it before the close of the last century. Desault is the first person who suggested the division moreover of the thyroid cartilage upon the median line, and it is to Boyer to whom we are indebted for the idea of incising at the same time from above downwards, the cricoid cartilage and the first rings of the trachea.

A. *Laryngotomy*, after the manner of Vicq-d'Azyr, and adopted by a great number of surgeons, possesses the advantage of being the most easy method, of acting upon a membrane which is but slightly organized and superficially situated, of not incurring the risk of wounding any vessel or any important organ, and of leaving the glottis intact; but on the one hand, it does not procure an opening sufficiently large to admit of the introduction of instruments required for the extraction of foreign bodies, while on the other hand, the canula which it would allow us to employ would be rarely large enough to admit of a sufficient quantity of air. In imitating Desault on the contrary, as has been done in America and in England, and as is also practised by M. Whitley and M. Blandin, we open into the larynx as freely as possible, and no vein or artery of

any size runs any risk of being divided. It is the only means in some sort of laying bare the foreign bodies, which in most cases become imbedded or arrested between the lips of the glottis, or the polypi or other vegetations, which also are rarely seen except in the vicinity of this part. Nevertheless, though the lesion of the *cordæ vocales*, which has been so much dreaded by those who have opposed Desault, may be easily avoided, and is moreover a matter of little consequence, and though the voice in patients treated by this method may not have suffered more injury than by any other, it does not however merit the preference, except in the cases which have just been pointed out; moreover, the patient should not have reached that time of life, when the thyroid cartilage has become charged to too great a degree with phosphate of lime. Should the dread of wounding the *cordæ vocales* deter him, the surgeon would have to do nothing more than to adopt the advice of *M. Fouilloux*, and in order to avoid them, divide the thyroid cartilage upon its side, and then lay open the soft parts of the glottis transversely. When the foreign body is situated below the larynx, or that it becomes advisable to insert a tube into the wound, it is evident that this process can no longer be applicable. Perhaps rigorously speaking, it might even be possible to replace it always by another operation which has been proposed by *M. Vidal* (de Cassis) with the view of opening abscesses of the glottis, and also by *M. Malgaigne*; an operation, the first suggestion of which no doubt was derived from the experiments of *Bichat* upon the voice, and which consists in penetrating into the larynx through the thyroid membrane. Nevertheless an operation of this kind has something in it repugnant, at least at first view, which admonishes me to dwell no longer upon it, notwithstanding it succeeded very well in the trials which I have made with it upon the dead body.

B. *Laryngo-tracheotomy*, which ordinarily leaves the thyroid gland entire, and which incurs the risk of wounding only the crico-thyroid artery, does not enable us, like the method of Desault, to examine into the bottom of the larynx; being too remote from the bronchi for foreign bodies, possessing but little mobility, to reach with facility the opening which has been made, the division at the same time is in too near proximity to the glottis, not to render the employment of a permanent canula dangerous; so that in spite of its inconveniences, tracheotomy still appears to combine the most advantages under all circumstances where the method of Desault is not absolutely required.

C. *Tracheotomy*.—The trachea, which is a sort of cylindrical canal which descends to a line with the second or third dorsal vertebra, and composed of about twenty cartilaginous rings and resting against the œsophagus rather more on the right side than on the left, is covered: 1st, by the common integuments; 2d, by the cervical aponeurosis; and 3d, by the uniting bridle of the thyroid lobes close to the cricoid cartilage; lower down by the supra-sternal venous plexus, and the middle thyroid artery when that exists; 4th, slightly upon its side by the sterno-hyoid and sterno-thyroid muscles. Accompanied posteriorly by the inferior laryngeal nerve, and at a considerable distance from it by the primitive carotids, it is sometimes crossed by one

of the thyroid arteries, which in that case goes from one side of the neck to the other. In infants especially, the trunk of the innominate almost always conceals its anterior surface, even as high up as above the thorax; so that the right carotid also does not leave it until at a point very high up, where it takes a situation completely on one side of it. I have also seen the left carotid originate upon the right side and pass in front of the trachea, in order to reach its usual destination, and that of the right side do the same. Other vascular anomalies also have been met with in this region, and deserve no less attention than the preceding. From all these relations it results that the trachea, which is sufficiently superficial above, where the thyroid gland, which protects moreover its lateral portions, alone almost separates it from the integuments, becomes deeper and deeper in proportion as it descends or inclines towards the chest in order to follow the thoracic concavity of the spine, and that at the lower part of the neck we are obliged to seek for it more than an inch deep under the integuments. Finally, from the great mobility it possesses we might very readily, when seeking to lay it open, if we were not on our guard, push it so much aside that the instrument might fall upon the primitive carotid, as happened in a case mentioned by Desault, and where it is seen that a pupil of medicine, who was in a state of asphyxia, was killed in this manner by one of his companions who was endeavoring to save his life.

I. The *ancient authors*, who recommended bronchotomy, restricted themselves probably like Antylus, to dividing transversely at the middle of the neck the integuments and space between the third and fourth rings of the trachea. J. Fabricius is the first person who proposed to perform the operation in two stages: first, to incise the soft parts from above downwards upon the median line, and then to open into the respiratory duct in the manner performed by the ancients. He recommends moreover that we should leave in the wound a small straight canula furnished with wings; a canula which Casserius caused to be slightly curved, which, according to C. Solingen, should be flattened, the external opening of which Moreau covered with a small portion of lint, and Garengeot with a piece of muslin, in order to intercept foreign bodies. In order to prevent its obstruction and not to be compelled to withdraw it when we wish to clean it, G. Martine found an advantage in inserting two, one within the other. Ficker, who adopts the idea of Martine, requires that the outer one should be made of silver and the inner of gum-elastic, and that both should possess a certain degree of curvature; finally, some moderns have maintained with Ferrein that it could be advantageously replaced by a portion of quill. The manner of inserting and fastening this canula has varied no less than its form. Sanctorius adjusted it by means of a trochar, and Dekkers inserted it into the trachea by dividing also the skin with the same instrument. Moreau made a passage for it between two rings by means of a simple lancet, and Dionis suggested that it should be conducted into the tracheal tube upon a probe. That of Bauchot is very short and flat, and its inventor, who moreover made use of a kind of crescent mounted upon a handle in order to steady the larynx, had, like Dekkers and Sanctorius, a stilette of the same form, with a cutting edge at its extrem-

ity, that it might traverse the skin and penetrate, by the same movement, into the trachea. Richter (*Biblioth. Chir. du Nord*, p. 234) incurvates the instrument of Bauchot into an arc, with the view of rendering it more supportable, and maintains, as M. Collineau (*Arch. Gén. de Méd.*, 2d ser., t. I., p. 589) has done since, that by means of the puncture from the wound of the trachea being immediately filled up by the canula, the hemorrhage becomes infinitely more difficult than by incision of the tissues. But this is an error, and whatever Bergier and B. Bell may have said of it, all these modes of arriving by a single operation into the canal, are at the present day generally and properly proscribed. The fear of wounding the *cartilages* also, again revived by Purmann, no longer attracts the notice of any one. Heister has clearly demonstrated that we may divide them without the slightest risk. Vigili of Cadiz who was obliged to divide them as far down as to the sixth ring in a soldier, in order to prevent the danger of suffocation which the ordinary incision had produced by causing an effusion of blood into the trachea, and who, in place of a canula, kept in the wound a piece of sheet lead curved upon its borders and perforated with holes, found no reason to regret it. Wendt, with the view of extracting the half of an acorn, ventured to incise three of these cartilages, and Percy on this subject advises that we should use the scissors instead of the bistoury, which latter however is much more convenient, and preferred with good reason by almost every practitioner.

II. It is doubtless already anticipated what are my views upon the importance of these numerous modifications of processes. In the first place, I would recommend the rejection of every kind of transverse incision. If the obstruction to be removed is a *foreign body*, the division of one of the intercartilaginous spaces will not prove sufficient, and if the object of the operation is to *enable the patient to breathe*, a wound of this description will never be found sufficiently large. If any other proof were found wanting, it would be found in a case operated upon in my presence in one of the large hospitals. The opening of the trachea had been well made and the canula properly adjusted, but it was a portion of gum-elastic catheter, and the patient compelled to breathe through so small a tube found himself partially relieved only of the suffocation, which it had been attempted to remove by means of the bronchotomy. In the first case the canulas and perforated plates are useless. As soon as the trachea is free we must reunite the wound or let it close up. If the foreign body is movable, the air of the lungs may expel it outwards. If it does not present itself spontaneously at the wound, we must proceed to search for it in the direction of the bronchi, by means of a pair of curved and delicate forceps or some other appropriate instrument. When it becomes impossible to reach it or meet with it, it must be abandoned, and the wound left open and the patient dressed. On the following day or the day after, it is generally found on the deep-seated surface of the dressing. Desault, Pelletan and Dupuytren have in this manner noticed the expulsion of a bean, kernel of fruit, piece of money, &c., and the needle that M. Blandin was unable to seize, after having divided the thyroid cartilage, also made its exit in the same way. In the second case the canula is indispensable, but as no author had

pointed out the importance of a *large and permanent* opening in the trachea, none of the tubes that have been proposed answer the purpose. That of M. Bulliard is cylindrical, long and strongly curved. M. Bretonneau has caused several successively to be constructed of various kinds. The canula which he used in Mlle. Puységur is double like that of Martine, and flattened, slightly concave on its inferior border, and four lines in breadth in its greatest diameter. That which he used in the patient whom I saw, is formed of two halves, one superior and the other inferior, which are placed separately in the wound, and which when once reunited, present no other than an instrument analogous to the preceding. M. Scoutetten, (Coqueret, *Thèse*, No. 185, Paris, 1834,) M. Lawrence, (*Ibid.*, p. 21,) M. Trousseau, M. Coqueret, (*Thèse*, No. 185, Paris, 1834,) M. Moreau, (*Gaz. Méd. de Paris*, 1838,) Boyer, (Coqueret, *Thèse citée*, p. 24,) M. Sanson, &c., have since contrived others; so that at the present day we possess those that are simple, double, flattened, cylindrical, eyed, cribbled, and bent into an angle or curved into an arc. In ordinary cases that of M. Bulliard is most convenient; under other circumstances we should have recourse to M. Gendron's, (see the Atlas;) the important point is, that it should be sufficiently large and frequently cleansed.

III. Whether we do or do not wish to make use of a canula, some persons have proposed that we should not restrict ourselves to a simple section of the cartilages of the trachea, but remove and *excise a flap of the anterior wall of this canal*. It appears that veterinary surgeons very frequently proceed in this manner. Andrée also appears to have followed this process, which is formally recommended by M. Lawrence, M. Porter, (*Dublin Hosp. Rep.*, vol. V., p. 560,) &c. But it is a precaution which is at the same time wholly useless as well as dangerous: useless, because the pure and simple incision always enables us to introduce the artificial tube; dangerous, because if it should become afterwards advisable to let the wound close up, there would necessarily result from it an incurable contraction of the respiratory passage. Consequently the process of M. Collineau, (*Thèse*, No. 676, Paris, 1829,) to accomplish this loss of substance, and at the same time to render every kind of hemorrhage impossible; a process which consists in perforating the trachea by means of a cutting-plate, making a projection upon the circumference of a flattened disc of copper heated to a white heat, and which is mounted upon a long handle, in my opinion appears to possess no utility, and ought to be abandoned, as well as the advice of MM. Carmichael and White, which has the same object in view.

### § III.—Operative Process.

A. The instruments for bronchotomy are composed of a straight or convex bistoury; a blunt-pointed bistoury; several canulas armed with threads, and everything which may be required to attach them; very delicate ring and polypus forceps; several simple ligatures and some needles; erignes or sounds curved in the form of hooks, and various articles of dressing. The patient being placed upon his back, should have the head only slightly reversed. Verduc has shown

that by inclining it too much backwards the respiration is rendered more difficult, a remark which is applicable, moreover, to all the modifications of bronchotomy. The surgeon being placed on the right, in order to incise from above downwards, and not from below upwards, as some persons recommend, grasps and steadies the larynx with his left hand, while with a convex or straight bistoury in his right hand he divides the tissues.

I. *Tracheotomy*.—In order that tracheotomy may be well performed, it is necessary that the wound of the soft parts should extend from the neighborhood of the cricoid cartilage as far down nearly as the sternum. After the integuments and aponeurosis we come to the vessels which are to be tied in proportion as they are divided; the veins of the thyroid plexus, which should also be tied when it appears impossible to avoid them; then the middle thyroid artery, when it exists, and which it would be dangerous to wound. When arrived upon the front of the trachea, should the blood flow in abundance and no necessity exist for haste, we may rest for some minutes in order that the respiration may arrest the hemorrhage; but if it is necessary to be rapid we hasten to pass threads around the vascular branches which bleed; or, what is still better, we immediately proceed to lay open the respiratory tube itself. Though the straight bistoury, held as a pen, is sufficient for effecting this opening, which ought to comprise at least the fourth, fifth, and sixth, if not the third and seventh cartilaginous rings, there are, however, practitioners who prefer the blunt-pointed bistoury to extend the incision after the puncture. I see neither any inconvenience or advantage in this: though even the point of the instrument should touch the posterior wall of the respiratory tube, which seems to be so much dreaded, there would probably result from it no very serious danger. This part of the operation being terminated, we proceed differently, according as we have to extract a foreign body or to relieve the suffocation. In the first case, should the body which is to be removed not be expelled instantly, then if it presents itself at the wound, whose lips the operator is to cautiously separate apart by means of the ring forceps or hooks, we endeavor to reach it with a suitable instrument, and to draw it out. When it remains immovable in the direction towards the bronchi, which, as Favier has shown, is quite rare, we insert, with every precaution possible, in this direction a suitable forceps or a small scoop, in order to detach or seize it. Should such researches prove unavailing, they should not be too often repeated. Should the surgeon have no other object in view than to establish artificial respiration, he immediately proceeds to adjust the canula. Having seized it, he places it in the trachea, while with the ring forceps he separates the lips of the wound wide apart. By conducting it upon a probe or canulated sound, which serves as an axis to it, I ordinarily succeed in introducing it into the wound without any difficulty. If during the operation the venous hemorrhage should be too abundant, and resist the ordinary means, we should not get alarmed and, in our fright, abandon the patient, as Ferand did in a similar case. If the patient is at the age of reason, we should soothe him and induce him to respire as freely as possible, when the blood soon stops of itself. Should any of it escape into the trachea and give rise to

accidents, it would be an additional inducement to imitate Vigili, and immediately lay open the respiratory tube largely, as I did in one instance successfully in 1838. We might also, after the manner of M. Roux, (*Lancette Franc.*, t. I., p. 182,) should the danger be pressing, apply our mouth on a tube or the end of a gum-elastic catheter, introduced into the wound in the trachea, in order to suck out the extravasated fluids which lead to the apprehension of suffocation.

II. *Cricoidean Laryngotomy*.—When we wish to lay open the lower part of the larynx the incision is to commence at the projecting angle of the thyroid cartilage, and descend a little below the cricoid, without the necessity however of making it as long as for tracheotomy. The surgeon divides in succession, or with one cut, the skin, subcutaneous layer, and aponeurosis; separates the thyroid muscles; places the pulp of his forefinger upon the crico-thyroid membrane; endeavors to feel the artery of the same name; raises it up or depresses it with his nail, according as he wishes to incise it above or below; plunges his straight bistoury, guided upon the nail of one of his fingers, perpendicularly into the membrane; turns the cutting edge of his instrument upwards or downwards, according as he has succeeded in pushing the arterial arcade to one side or the other, and makes in this place an opening of the proper dimensions.

III. *Laryngo-tracheotomy*.—In order to transform the preceding operation into laryngo-tracheotomy, as M. Duchateau (*Thèse*, Strasbourg, 1823,) has in one instance successfully done, we have nothing more to do than to insert a blunt-pointed in place of the straight bistoury, and to enlarge the wound from above downwards by dividing the cricoid cartilage and first rings of the trachea upon the median line.

IV. *Thyroidean Laryngotomy*.—The same instrument directed from below upwards accurately upon the median line, would serve full as well to separate the two halves of the thyroid cartilage, after the manner of Desault. Upon the supposition that in spite of every precaution possible, the *crico-thyroid* artery has been divided, and that it may give rise, which is difficult to comprehend, to an alarming hemorrhage, it could be easily surrounded with a ligature upon its right and left, and it surprises me that a vessel of so little importance has attracted so much attention. The little finger inserted into the wound is first made to proceed in search of the foreign body, and then serves as a director to the forceps or other instruments which it may be deemed advisable to employ. As soon as the body is removed, the wound is to be reunited by first intention, and the cure is generally effected in a very short time. When, however, we have not been enabled to find it, the wound is to be left open and we proceed afterwards in the same manner as in tracheotomy. In my opinion, moreover, the *suture* recommended by some authors and used by Herhold, ought never to be made trial of, whatever Delpech and M. Serre say of it. The patient mentioned by Wilmer, and in whom it was made use of, died suddenly on the fifth day after the operation. It can only have a tendency, in such cases, to favor the extravasation of sanguineous or other fluids, either between the air passage and the tissues which surround it, or into the interior of this

canal itself, while the other containing means are always sufficient for reunion in a wound of this description.

V. *Thyro-hyoidean Laryngotomy*.—After having laid bare the thyro-hyoidean membrane upon the median line, by means of an incision about two inches long, it will be found less difficult than might be supposed, to reach the superior cordæ vocales, provided we divide it transversely above the cartilage which gives attachment to them. A bistoury plunged in at this point from above downwards and from before backwards, traverses the root of the epiglottis, falls immediately into the larynx, thus making for the finger or forceps a passage, which can be enlarged at pleasure, and which enables us to pass round the whole of the glottis without wounding in any way whatever either the cordæ vocales or the cartilages. No artery of any size nor any important nerve can be wounded. The laryngeal branch of the superior thyroid artery and the corresponding nerve are sufficiently distant from the median line, to enable us to avoid them with ease, and no venous plexus is encountered at this point. The wound made by this operation might have, I should think, some tendency to remain gaping open, but it is probable that in living man the inflammation would speedily approximate its borders, and that cicatrization would be effected without difficulty.

B. If our intention is to restore the respiration of the patient, and not to extract any foreign body from the aerial passages, the surgeon having satisfactorily removed the suffocation, has still to attend to two things, to wit, the disease of the larynx and the canula which he has left in the wound. Under the first point of view therefore he will have recourse to antiphlogistics, general or local, to resolvents, detergents and even caustics, either by the mouth, or on the skin or wound, and to blisters, antisyphilitics, &c., according as the disease may be laryngitis, croup, ulcers or a venereal affection of the larynx. As to the canula, it is important to have at least two of them, and that they should be changed or cleansed as often as the respiration appears to be incommoded. They are to be kept in place by means of two ribbons of some breadth, which are to be crossed on the nape and brought forward to be attached by a bow-knot in front of the neck at the supra-sternal fossa. Patients should wear this canula as long as the air does not pass freely through the glottis. There are some, moreover, who dispense with them without danger at the end of the first or second month, while there are others who have to wear them for one or several years, and even during all their lives.

#### [LARYNGOTOMY AND TRACHEOTOMY FOR FOREIGN BODIES, CROUP, ETC.]

There will doubtless be sufficient time to make improvements in the method and instruments to be employed in laryngotomy, and in tracheotomy, for croup, &c., after the operation itself shall have ever received the sanction of the profession, under any circumstances except for the removal of foreign bodies. Though the *pathological* condition of the system, which results in the production of the false membrane in croup, even throughout every ramification of the bronchial tubes, has no parallel with the perfectly sound state of the air passages, when foreign bodies have become lodged there, still the

restless impatience of innovation is such, that some surgeons have already, before the propriety of the operation in croup, *at all*, is yet decided upon, begun, like Dr. Morand among others, (*Recueil des Travaux de la Soc. Méd. d'Indre et Loire*, in *Gaz. Méd. de Paris*, 1846, XVI. année, 3e sér., t. I., p. 210.) to refine upon the character of the wound and the nature of the instruments required to perfect the process in question. Thus, to prevent asphyxia, and the desiccation of the mucus of the passages, and the better to reach and draw out the glove-like prolongations, he proposes to *open into the trachea largely*, also to dispense with the canula, and to *dilate* the wound by instruments for that purpose, and then to place over it a thin gauze, in order that it may become moistened by the air expired. The dilatation of the wound must expose to greater hemorrhage, and therefore to greater danger of blood passing into the trachea, and strangulating the patient. As to the hope of thinking to extract the false membrane after it is once formed, it appears, in our judgment, altogether chimerical.

Mr. Lawrence thinks laryngotomy by a small aperture, with the two-edged bistoury, into the crico-thyroid membrane, quite sufficient, and preferable to tracheotomy in all cases where we desire to obtain artificial respiration. The former is unattended with danger, while in the latter we may have serious hemorrhage from the thyroid veins, (*London Med. Gaz.*, June 20, 1845.) But the serious character of the hemorrhage, as we have explained in our notes, arises from the danger of some particles of blood getting into the trachea, and causing immediate convulsive strangulation, suffocation, and death. This is most to be apprehended in children, wherever the opening may be made, as the vessels, especially the veins, become enormously distended, and enlarged, and engorged, by their cries and struggles, as in the case (*vide infra*), of the removal of a large dressing or shawl pin by Dr. Mott. Mr. Coote, in examining the false tubular membrane in a case Mr. Lawrence operated upon, found it to be a yellowish soft coating, extending throughout the minutest ramifications of the bronchi of the left lung. This adult had been laboring under bronchitis. (*Ib.*, loc. cit.) Mr. Coote ascertained that the membrane constantly preserved its *tubular character*, that it was of the thickness of the mucous membrane, and that it consisted of *pure fibrine*. Mr. W. Chapman, on the other hand, in a case of acute laryngitis, (*Lond. Lancet*, June 7, 1845,) made his incision longitudinal, and half an inch long, and just one inch above the sternum, and then introduced the tracheotomy trochar and canula. He insists that this is the best place in such affections, and especially because we thereby save the patient from the irritation caused by air passing *over the inflamed surface of the larynx*. He properly insists that it should be performed early, and before the last suffocating stages have arrived. This, we perceive, by what takes place in respect to the deposition of the false membrane above, is correct reasoning. Mr. Chapman saved and cured his patient. Mr. Liston also prefers *tracheotomy* in all diseases of the larynx and glottis, and in a majority of the cases of foreign bodies in the air passages, especially if they are in the trachea, (*London Lancet*, Nov. 23, 1844.) His object is to have a large opening, and also in laryngitis

to get below the disease. Where the canula has to be left in, Mr. Liston says the patient can generally clean the tube of mucus by putting the finger partially over the outer end of the tube, so as to narrow it, and excite resistance to the expiration, and thus promote a slight cough, (*Ib.*) A double canula allows you to clean one while the other is left in.

M. Vogelvanger (*Annales de la Société de Méd. d'Anvers, Gaz. Méd. de Paris*, and also the *Provincial and Med.-Surg. Journ.*, May 27, 1846, p. 217,) succeeded, in 1840, in extracting a large slice of a carrot, nearly an inch and a half in length, which had become impacted or wedged into the upper part of the larynx, in a girl between five and six years of age. As the incision into the trachea afforded relief to the respiration, as a return of suffocating symptoms took place when the wound was closed, and as the body could not be seen, the surgeon naturally thought this latter was above the wound made. Introducing, therefore, a dressing forceps upwards, the portion of carrot was immediately extracted, and the patient's life thus saved.

A remarkable and instructive case in which tracheotomy was performed, is one which occurred in the practice of Mr. J. Elkington, at Birmingham, England, (*Provincial Med. and Surg. Journ.*, April 22, 1846, pp. 184, 185.) The patient, a woman aged twenty-six, in the ninth month of her pregnancy, was seized, January 6, 1846, with a croupy cough, bloody expectoration, and loss of voice, which increased, together with suffocating paroxysms to such degree, that the trachea was opened at the usual place, January 17, which gave much relief. The same evening labor came on, and on the next day, January 18, she was delivered of a dead child without any difficulty. On the morning of the 19th she slept two hours. The breathing being then worse, the canula was removed, and at half past three, P. M., an attempt made to enlarge the opening, by which means a *vein was divided and some blood got into the passage*. At four a *dreadful convulsion* came on, and she expired. The appearances after death presented a false membrane of coagulum lymph on the entire *mucous lining of the air passages, larynx, trachea, and bronchial tubes, down to their smallest ramifications*. Here is an unequivocal and aggravated case of croup, in which leeching and other depleting and antiphlogistic measures do not appear to have been carried sufficiently far. This case also calls up again the subject of the extreme danger of the entrance of the blood into the trachea in tracheotomy, (*vide infra*.) and the question, how far the attempt to enlarge the wound may have led to the immediate fatal result.

A foreign body will play up and down in the *trachea* like a pea in a quill, for weeks, without other inconvenience than occasional fits of coughing. Finally it will become permanently lodged, probably in the *rima glottidis*, and may there suddenly cause death by suffocation during an access of coughing, as in the case of a pebble swallowed by a little girl, between two and three years of age, as related by Mr. Pitcher, (*Lond. Lancet*, 1844,) and also in the case of an infant, mentioned by the same surgeon, and in whom a piece of cabbage stalk was found, after death, to have got imbedded between the *cordæ vocales*. Laryngotomy would have saved both, perhaps.

The same surgeon, (*Ib.*) called to a child who had swallowed a tamarind stone, at once proceeded to open the trachea, but found no evidence with the forceps of any foreign body. Bronchitis ensued, and under the supposition that the operation might have caused this, the wound was closed up. Death followed, and a tamarind stone was found imbedded in the upper part of the right lung, having passed through the right bronchus. The lung was one mass of disease, and in quite a pulpy condition.

A girl aged 16, at the city of Dublin Hospital, is stated by Dr. Houston, (*Dublin Med. Journ.*, 1844, vol. XXV., p. 532, &c.) to have swallowed, about a month before Feb. 1841, a fragment of wood, while laughing with it in her mouth. She suffered especially at night from fits of coughing, and had a constant mucous rale, with stridulous croupy breathing. The coughing however, was always relieved by a sup of any liquid. Tracheotomy was performed by Dr. Houston, May 19, which brought on a violent paroxysm of coughing, probably from inattention to accurate sponging of the wound, and previous careful ligature or torsion to all the vessels, so as to prevent the slightest introduction of blood into the tube. [See what we have elsewhere said of the opinion of Dr. Mott, on this point.] During a violent paroxysm, and not until the month of August, was the fragment thrown up, which proved to be a *wooden peg* of a *boy's fiddle*, after which she recovered rapidly, though in fact her general health had never been impaired. It is remarked in this and all other cases, that the upper parts of the air tube about the glottis may be freely explored without causing any irritation, whereas it is the reverse in the direction towards the bronchi. In a child aged six years, a small brass nail, such as is used by upholsterers for covering chairs, got impacted with its point upwards into the sinus of the ventricle of the larynx, and with its head downwards below the glottis, and soon terminated in death, notwithstanding the operation of tracheotomy by the surgeon, Mr. Richeley (*Dublin Med. Journ.*, vol. XXV., 1844, p. 516,) asphyxia unfortunately having taken place before surgical relief was sought for. No mention is made of exploration of the larynx.

In confirmation of the above case, in which a fiddle peg remained for so long a time in the trachea, and also in proof of the necessity of our being on our guard against any hasty inference that no foreign bodies have been introduced, or that they have been discharged, merely because the suffocating paroxysms are immediately arrested by the swallowing of any liquid, we may remark that a similar, but much less aggravated case occurred to Dr. L. Pagen, (see M. Capuron, in *Arch. Gén. de Méd.*, 3d ser., t. VII., 1840, p. 369,) of France. A young child while playing with some beans, got one into the larynx, which caused symptoms of suffocation, but which were immediately calmed as if by enchantment, by giving it a *tea-spoonful of olive oil*. This remedy succeeded in the same manner, as often as the paroxysms supervened, until finally, at the expiration of *forty days*, the bean was expelled in fragments, by the efforts of the child itself. Where patients or parents will not submit to an operation, and where the danger is not imminent, we are thus at least furnished with a temporary

resource of great value, and which may in fact aid in accomplishing the ultimate spontaneous removal of the difficulty.

M. Petel, who has been (see *Arch. Gén. de Méd.*, 3e sér., t. XIII., 1842, p. 361, 362) one of the earliest advocates for tracheotomy as an extreme remedy in croup, and who cites three cures which he effected by this process, prefers for the operation the bivalve canula of M. Gendron, as modified by him. (*Journ. des Conn. Méd. Chir.*, October, 1841.)

Of late years many efforts have been made to introduce or revive tracheotomy for croup by MM. Bretonneau, Trousseau, and others, (see Valleix in *Arch. Gén.*, Oct. 1844, p. 256, et seq.) The operation will not be sanctioned in our opinion, for the following reasons: 1. As it cannot properly be substituted in the first stage, for a vigorous plan of antiphlogistic, emetic, and revulsive treatment, (viz., venesection, large blistering, leeching and emetics,) it will be had recourse to only in the last stage, merely to prevent immediate suffocation, and thus prolong life for a few hours. 2. Because it is an operation which is generally contra-indicated, and properly proscribed under any circumstances, or in any disease whatever at the period of infancy, or that when croup mostly occurs. This is because of the danger of either laryngotomy or tracheotomy, in them, as the smallest drop of blood passing from the incision into the trachea has been known to produce immediate strangulation and death. This accident is the more to be dreaded from the great vascularity of the parts, and the extreme distension of the veins, and therefore more abundant hemorrhage caused by the cries and struggles of the child during the operation; showing how incorrect it is in a surgeon of Paris to recommend, as has been done recently, with the utmost nonchalance possible, such an *innovation* even of tracheotomy as that of *direct puncture* through the crico-thyroid membrane by means of a trochar, with a cutting spring forceps inclosed, this too with the patient on his back. 3. Because in no sense could tracheotomy be justifiable as a *remedial* measure for croup, because in the first stage it would necessarily aggravate the symptoms, and again in the second stage, after the formation of the *finger of glove-like tubular membranous prolongations into the bronchi and their ramifications*, death could not possibly be averted by it. In illustration of the above remarks, we refer to the remarkable case of the successful extraction of a shawl-pin from the trachea by Dr. Mott. (See *Infra*.)

M. P. Jousset had already (*Arch. Gén.*, 4e sér., t. V., August, 1844, p. 402—416,) done full justice to the subject of tracheotomy in croup. As interne at that time in the Hospital des Enfants, at Paris, he had admirable opportunities of demonstrating the true character and structural ravages of croup and the inefficacy of surgical means. M. Jousset shows that the operation under the name of *bronchotomy* was performed at the remotest period of time, and for croup under the name of *angina gangrenosa*. Hence the mistake of the moderns, in thinking the disease and the operation both new, whereas M. Jousset clearly shows, that our own countryman, Dr. Samuel Bard, (*Ib.*, p. 401,) of New York, had many years since satisfactorily demonstrated that as respects the disease, the *angina gangrenosa* of the older authors was identical with croup. Out of 219 cases of the

operation, from 1782 to 1844, as collected by M. Jousset, it is ascertained that 40 only terminated in cures; while he has verified from the time of Galen to the present epoch 35 cases of croup or angina, which recovered by medical treatment exclusively, and that even after the expectoration of false membranes, of which 35, *ten* were cases in which false *tubular* membranes themselves were discharged. The practice of Van Swieten therefore, in favor of early tracheotomy in croup, undoubtedly the most rational period, and that of Louis, who after him considered it the only cure at any stage of the disease, as well as the modern advocacy of the operation, are wholly and vehemently proscribed by M. Jousset, except as an extreme and last resort to prevent immediate suffocation. In two such cases even it was in his hands followed by a cure.

*Tracheotomy in Spasmodic Dyspnea from Bronchocele.*—Dr. Handyside, of Edinburgh, (Cormack's *Monthly Journ.*, &c., Jan. 1845, p. 30, &c.) in the case of a young man, aged 18, with hypertrophied condition of the thyroid body (bronchocele,) to great extent, causing distressing attacks of dyspnea and bronchitis, obtained immediate relief by cutting down through the right portion of the diseased gland to the trachea, which was displaced by it, and inserting a tube in the opening made into the windpipe. The profuse venous hemorrhage however, which followed, and which it was found difficult to restrain, had no doubt much to do in this case in allaying the pulmonary disease, and in promoting free muco-purulent expectoration, and ultimately, in about two weeks a cicatrization of the wound and almost total absorption of the enlarged thyroid body. The case however is one of much interest surgically, and the operation was the true cause of its successful termination.

*Spontaneous Expulsion of Foreign Bodies from the Air Passages.*—In addition to the well-attested cases of the length of time during which such bodies may be retained in the trachea or bronchi, causing there chronic inflammation, and purulent or bloody expectoration for two or three years, and then be finally expelled by efforts of coughing, we may mention that of a man aged 42, mentioned by Dr. Duncan and Dr. Spence, (*Northern Journal of Medicine*, Aug., 1845.) This person letting slip two pieces of bone into his trachea while at dinner, in February, 1841, became affected with the symptoms as above described, which continued till March 2nd, 1845, when during a violent paroxysm of coughing he expelled the foreign bodies, one of which was rhomboidal and an inch long, and the other a slender fragment of nearly the same length. By June of the same year he had perfectly recovered. In another case, a boy aged  $5\frac{1}{2}$  years, while chewing an ear of grass in a field, got the same into his trachea in 1840, when he was attacked with the usual inflammation and expectoration of pus and blood, which finally threatened hectic fever, until during a violent fit of coughing 22 months afterwards, the foreign body was expelled. It was an entire ear of the crested dogstail grass. The boy recovered perfectly, (*Ib.*, loc. cit.)

M. Ehrmann, of Strasbourg, (*Arch. Gén.*, Mai, 1844,) had recourse, with success, to an incision into the trachea in a woman, for the purpose of extracting a *fibro-cellular polypus*, the upper part of which had extended up between the lips of the glottis. The whole

length of the lower left ligament of the glottis was closely grazed off by the bistoury.

*Foreign bodies in the Pharynx.*—Mr. R. Jackson, (*Edin. Med. and Surg. Journ.*, July, 1843,) describes a case of suicide in a woman, aged 42, who *designedly swallowed a key*, which lodged behind the glottis, with its ring part downwards. The severe inflammations in the air passages, with the abundant expectoration which ensued, but without deglutition being much interrupted by the foreign body, caused death in a few weeks. A very similar case occurred in a man named Gilbert. Dr. Handyside, also, has given cases (*Ib.*) of foreign bodies lodged in the pharynx; in one the body was rejected during a paroxysm of vomiting. (See notes under the head of *Œsophagus*.)

*Pharyngeal Fistula.*—Professor Albers, of Bonn, had the rare opportunity of examining (see *Graefe's und Walther's Journal*, Bd. XXX., Heft 3; also *Arch. Gén. de Méd.*, 3e ser., t. XIII., pp. 489, 490, 491,) in the year 1841, a case of pharyngeal fistula, immediately above the os hyoides, near the angle of the jaw, two inches in height and one in breadth, in a German soldier, aged 41. It was caused by a sabre wound, in the campaign of the French against Constantine, and, except for the first few weeks, during which its edges were cicatrizing, had not prevented him from following the active life of a soldier and engaging in other battles, in some of which he has been again wounded. He wears a leather strap over the fistula, and without this can neither swallow, articulate, or cough. When it is removed, he breathes through this large aperture only, and a good opportunity is then afforded of observing the position and play of important parts in life and robust health, as that of the velum and arches of the palate, the epiglottis, glottis, larynx, &c. No attempt appears to have been made to cure the deformity.

*Bronchial Calculus.*—Dr. S. C. G. Tice describes, (*Medico-Chirurgical Trans.*, vol. XXVI., London, 1843, 8vo.) an interesting case of bronchial calculus, the symptoms of which were pain in the right side, increased by pressure over the liver, dyspnœa: finally, suffocating paroxysms of cough on lying down, great fetor of breath, ending, after a continuance of six weeks, in laryngitis and sudden death. There was nothing before this event to indicate the true nature of the disease. On examining the body, an abscess, of the size of a pullet's egg, was found in a mass of enlarged bronchial glands at the bifurcation of the trachea. It opened into both bronchi, and into the œsophagus, and contained a quantity of *calcareous matter*, some of which was hard and some of soft consistence. A hard triangular portion was firmly wedged in the aperture, communicating with the right bronchus. This was found to consist of phosphate of lime. (See also *British and Foreign Med. Rev.*, vol. XVIII., July—October, 1844, p. 365.) T.]

## ARTICLE II.—CATHETERISM OF THE LARYNX.

Catheterism of the larynx, whether in new-born infants or at any other epoch of life, is too simple an operation to require to be described more in detail. While with one hand the instrument is con-

ducted through the nose, or what is better, through the mouth, some of the fingers of the other hand, directed upon the lower part of the throat, secure its extremity, bring it into the glottis and prevent its passing into the œsophagus.

## CHAPTER IV.

### ALIMENTARY PASSAGES.

#### ARTICLE I.—CATHETERISM OF THE ŒSOPHAGUS.

Various kinds of affections may render it necessary to have recourse to catheterism of the œsophagus. It is employed either as an exploring, extracting or propulsing remedy; it becomes an indispensable operation when we have to penetrate into the stomach to give relief in cases of certain poisons, or to force into this organ artificially, either aliments or medicated substances, and it may be of some advantage also in the treatment of certain diseases of the œsophagus itself. Its manual is easy and within the capacity of any one. It may be accomplished through the nose as well as by the mouth, by means of metallic instruments properly curved, and especially with flexible rods, such as canulas, gum-elastic bougies, whalebone, &c.

#### § I.—*Through the Nose.*

The first method, or that which consists in entering through the nasal fossæ, and which was adopted for a long time as the preferable one, is at the present day almost entirely abandoned. Being frequently difficult, and always fatiguing to the patient, it should be reserved only as an exceptional method. If the catheter is inflexible (fixe) its curvature will scarcely allow it to go beyond the apex of the pharyngeal cavity, and consequently to penetrate into the œsophagus. If it is flexible and straight, it butts against the vertebral wall of the posterior fauces, in such manner as to make it sometimes difficult to disengage it. This route however is better than none, should the other not be practicable. The sound, held in the right hand as a writing pen, is introduced through the nares in the same manner and with the same precautions as for catheterism of the Eustachian tube, except that the concavity of its beak, in place of being turned outwards or inwards, is rather to be directed downwards. By means of the forefinger or a blunt hook glided into the mouth, the operator endeavors to reach its extremity as soon as it arrives in the upper part of the pharynx; depresses it a little with the left hand, while with the right he continues to push it forward; in this manner directs its point into the axis of the œsophagus, while avoiding with care the entrance of the larynx or making too much friction on the parts; penetrates and advances by degrees; stops upon encountering the slightest difficulty; changes a little the direction of the force applied; withdraws

the instrument slightly in order to push it in again in another direction, if he meets with any resistance, and descends to a greater or less depth according to the indication he proposes to fulfill. Upon the supposition that a straight elastic catheter should have occasioned some embarrassment, nothing would be more easy than to remedy this inconvenience; it should be passed down to a line with the glottis by means of a curved stilette, which should then be withdrawn, leaving the catheter in and proceeding in such manner for the rest of the operation as above described.

## § II.—*By the Mouth.*

Whatever may be the mode adopted, the patient being seated on a chair, is to be supported as in all other operations which are performed upon the face. When he enters by the mouth the surgeon gently depresses the tongue with the left forefinger, which he introduces, if possible, as far down as to the epiglottis, in order to protect him against the deviations of the instrument in the direction of the respiratory passages, then causes the sound or catheter to glide along the radial border of this finger while following the dorsal surface of the tongue; enters without difficulty into the œsophagus if it presents the slightest curvature; secures its extremity with the finger in the contrary case in order to compel it to follow the axis of this canal, and finally forces it to take such course as he judges most suitable.

When circumstances require that it should be kept in its place after the operation, it is to be inclined to one side in the interval left between some of the teeth, should any have been extracted, in order that we may adjust it at one of the labial commissures, by means of a ribbon which is to be fastened moreover around the head. Though it has been introduced by the mouth, should its presence cause too much fatigue to this cavity, nothing would prevent us, as has been remarked by Boyer, from bringing its outer extremity through the nose and thus changing the organ. All that would be required for this purpose, when it is once placed, would be to secure it by means of Bellocq's sound or any flexible bougie whatever, introduced through the nose, and to make traction upon it by means of a thread previously fastened to its extremity, in the same manner as would be done in tamponing the nasal fossæ. Unless the œsophagus should be deviated, contracted or abnormal, its catheterism is in general very simple. We should incur no risk of wounding its walls, making a false passage or blundering, in a word, or perforating it, as happened to the surgeon mentioned by Chas. Bell, unless we should proceed with extreme imprudence or use a degree of force that no instructed surgeon would attempt to employ. The finger being charged to guide the catheter as far down as to beyond the epiglottis, there can be no difficulty in ascertaining whether it has not accidentally descended into the larynx, as appears to have happened in the case mentioned by Worbe. Presenting a light at the orifice of the instrument, or the impossibility almost of its penetrating lower down than on a line with the bronchi, or better still, the injection of a few drops of liquid, which in that event would not fail to bring on cough, &c., would moreover soon assure us of the fact.

## § III.

The presence of an instrument in the œsophagus is not supported with ease by all persons. In some it produces a desire to vomit, a considerable degree of acute irritation and sometimes even fever. If still more serious accidents result from it; however useful it may be, it is to be withdrawn to be introduced subsequently, should there be occasion for it. One of its most serious inconveniences, though authors have scarcely made mention of it, consists in my opinion in this, that either by its beak or the convexity which we have forced it to take, it necessarily makes a greater pressure upon some points of the posterior wall than upon any of the others. This pressure, however slight it may appear to be, being uninterrupted, is calculated to cause at first a purulent exudation, then an ulceration or eschar, and finally a perforation. It would be difficult to call in question the possibility of such dangers, when we know that they have been produced in more than one instance by the extremity of a simple gum-elastic sound acting on the rectal wall of the urinary bladder. I strongly apprehend moreover, that the patient, whose œsophagus was found destroyed to the extent of at least two inches at an inch and a half above its passage through the diaphragm, and who had been treated by means of dilating sounds with apparent success, by M. Carrier, was in truth the victim of such an accident.

## ARTICLE II.—CONTRACTION OF THE ŒSOPHAGUS.

Since Mauchart has demonstrated the analogy which exists between the coarctations of the urethra and those of almost all the mucous canals, surgeons have endeavored at different times to apply to the contractions of the œsophagus, most of those remedies which have been found useful against those of the excretory duct of the urine. Mechanical dilatation was one of the first which was ventured upon. Recommended by Richerand and Dupuytren; made trial of on one occasion by MM. Carrier and Jallon, in a merchant of Orleans, who got along very well with it for more than a month, but ultimately perished from a destructive ulcer in the œsophagus; employed by Boyer, in the year 1797, in a woman who experienced but slight advantages from it, and by M. Sanson on a patient who, after having obtained much benefit from it, was desirous of leaving the Hotel Dieu, and considered it no longer necessary to continue under treatment; it appears to have been attended with a completely successful result in a case of Migliavacca, cited by Paletta; in another of E. Home; a third of M. Earle; a fourth of M. McIlvaine, and a fifth of M. Denis, (*Journ. Hebdom.*, 1835, t. II., p. 5.) Catheterism is the process used. The bougies, whether emplastic, elastic or conical rather than cylindrical, or better still, hollow sounds denominated *œsophagean*, used in such manner that their size may be gradually augmented, should be manipulated in these cases with the same caution and prudence as when used in the urethra. But the canal being larger or being intended to receive greater dimensions, the size that we are soon obliged to give to these instruments has placed us under the necessity of substituting other contrivances for them.

A contraction produced by an abscess which had left an œsophago-tracheal fistula, was cured by M. Gendron, (*Ibid.*, 1836, t. I. p. 378,) by means of a dilating sound sprinkled with alum. The author upon the strength of this fact and another, which was communicated to him by M. H. Bérard, (*Journ. des Conn. Med-Chir.*, Nov. 1837, p. 175, 187,) proceeds to lay it down that contractions of the œsophagus ought to be treated, and may be cured by catheterism. The instrument of M. Fletcher is curved and slender, and of metal, and consists of three branches, which a central rod provided with a head enables us to approximate or separate at pleasure. After having introduced it like an ordinary catheter, beyond the point of coarctation, it suffices to cause its movable axis to ascend, to enable the surgeon to separate its branches gradually to the extent that he may judge desirable. However ingenious this instrument may appear, it ought to be rejected. It is by means of a uniform pressure, and not at three points only of the contracted periphery, that dilatation can offer any prospect of success. It is necessary before all other things, that this indication should be perfectly fulfilled, but M. Fletcher appears to have entirely overlooked it. The air dilatator of M. Arnott, or the flexible and sheathed meche-holder contrived by M. Costallat, in order to reach deep-seated coarctations of the rectum, and especially of the urethra, would have a decided preference over it. Many surgeons also have turned their attention towards cauterization. Though among us this mode of treatment has been rarely made trial of, and that Boyer has thought proper formally to proscribe it, it is not however the same in other countries. M. Mondière, (*Arch. Gén. de Méd.*, 2nd ser., t. I., p. 465, t. II., p. 504, t. III., p. 28,) in fact shows that in Italy, England, and America, it has been several times had recourse to. A flexible rod, wrapped in linen saturated with liquid caustic was introduced by Paletta as far down as to the stricture, and the patient who died some weeks after found himself at first relieved by it. E. Home properly rejecting every substance of a fluid character, preferred nitrate of silver, and used it in seven instances. Four of his patients were cured, and the three others died from the natural progress of their disease. Out of three cases published by M. Andrews, one only succeeded. In the two others the treatment could not be continued. Finally, MM. C. Bell and MacIlvaine also declared themselves its partisans as Darwin had previously done, and appear to have made use only of nitrate of silver. A difficulty which first causes us to hesitate, is that of ascertaining the nature of the contraction which is to be overcome. Those only which arise from chronic phlegmasia, or an induration or lardaceous transformation of the mucous tunic or suprajacent membrane, admit of the employment of cauterization; but how are these to be distinguished from lesions which may be produced by tumors, cancerous or fungous degenerescences, ulcers of all kinds, aneurisms, polypi, &c.? The urethra being, so to speak, liable only to the first, incurs the risk of no embarrassment of this kind. Its small diameter, superficial situation, and the arrangement of its walls moreover, renders its mechanical dilatation an easy matter, and unattended almost with any danger. The œsophagus being surrounded with pliant tissues, and being itself exceedingly dilatable, is far from possessing the same advanta-

geous conditions under this point of view. By widening the contracted part, bougies scarcely do any more than to push outwardly the projection which was tending inwardly, and the disease returns almost as soon as the use of the instrument is suspended, making it therefore only a palliative treatment. As to the nitrate of silver, I would use it much less in its character as a caustic, than with the view of modifying the morbid condition of the parts; in this respect, the exactitude with which it is applied to this or that point in preference to another, is of less importance than is supposed. This, moreover, is a question which will be treated of under the head of diseases of the urethra.

[*Organic Stricture or Contraction of the Œsophagus.*—This distressing disease, which usually ends in a slow death by inanition or starvation, has naturally engaged much attention. M. Gendron furnishes one of the most interesting cases of cure of this disease, obtained by perseverance under every obstacle of the processes of alternate dilatation and cauterizations with alum and nitrate of silver; the dilatations being effected by the ordinary whalebone probang, made very flexible, with spherical sponges on their extremity of 6 to 7 centimeters in diameter, and the cauterization by the gum elastic canula with the wax border, to protect other parts than the structure itself from the action of this substance. The patient, a gentleman 33 years of age, had been for near two years the victim to distressing suffocating spasms in the throat and gullet, accompanied with still more annoying and prolonged attacks of eructation after taking his food. Finally, he could swallow nothing but soft-boiled meat, and *scarcely a drop of liquid*. The necessity of abstaining from nourishment soon wasted him away, and the thirst tormented him with agony. M. Gendron, (see *Arch. Gén. de Méd.*, 3e ser., t. XV., 1842, pp. 448, 457, also cases by the same author in the *Journ. des Connaiss. Médico-chirurgicales* de Paris, Nov. 1837,) by the probang, and especially by aiding this instrument with his fingers in the pharynx, whenever the sponge was stopped and the whalebone bent on encountering the impediment, succeeded in localizing the seat of this latter behind the first ring of the trachea. Meanwhile great relief was obtained by introducing any kinds of liquid food through the canulas used. The proof that duplicatures, as well as a firm bridle existed at the point, was shown by the greater difficulty of swallowing liquids, as these are caught by such folds in the lining membrane. The caustic brought away the debris of the abnormal obstruction, and the patient was after a long and resolute course of treatment by the instruments in question, restored to excellent health, enbompoint and cheerfulness, but still was under the necessity of persevering in the catheterism with the probang twice a week, to keep up the calibre of the passage to its normal dimensions. The flatulence, spasms, &c. were wholly removed. It is a singular feature of these circumscribed strictures, that they are unaccompanied with any defined pain in the part or vicinity. Though with most surgeons catheterism and cauterization of the œsophagus have been considered of late, to be more hazardous and injurious than useful, there can be no doubt, judging by the details given by M. Gendron, that much of the disrepute into which they have fallen has

arisen from the imperfect manner in which they have been performed; and that if practised as perseveringly and with as much apparent judgment, caution and tact as they were in the remarkable case in question by that surgeon, they will claim a yet higher reputation than they have hitherto reached, in a disease, which without some such surgical resource must necessarily end in a frightful death.

The œsophagus sometimes becomes preternaturally dilated, as in the case related by Dr. Lindau of Thorn, (Casper's *Wochenschrift*, 1840, No. 22,) in the form of a pouch occupying all its middle and posterior portion, and no less than four inches in diameter at its largest expansion, the whole of this sacculated diseased mass being adherent to the surrounding parts. Whether such pouches be the result, in the first place, of cancer, and then a constriction interrupting the food, and thence giving rise secondarily to dilatation from the efforts in deglutition; or whatever the cause may be, it will be found that one diagnostic mark will present itself after the dilatation is complete, which is the reverse of what we have seen in the case above. Thus, in dilatations it will be the *most liquid* kinds of food which will make their way most readily into the stomach, while the solid portions from the absence of propulsive power in the tube will continue to accumulate in the pouch. T.]

### ARTICLE III.—FOREIGN BODIES IN THE ŒSOPHAGUS.

A crust of bread, a piece of tripe, large mouthfuls of hard and tough meat or skin, a slice of fruit, a sugar-plum, a piece of mutton, cake, a slice of ham, an entire egg, a chesnut, pear, fig, and all other substances that may possess some solidity, and which belong to articles of food, or that are sometimes introduced into the mouth, may be arrested in the œsophagus and give rise to serious accidents. As these different bodies, however, are more or less soluble in the excretions of the digestive passages, it rarely happens that they do not ultimately descend into the stomach. Pebbles, pieces of glass, a fish or other small bone, a piece of money, a blade of a knife, a fork, and a thousand different modifications of foreign bodies, so many instances of which are contained in the memoirs of Hévin and Sue, are infinitely more dangerous, though the organism has in more than one instance got the better of them without any assistance. They lacerate or contuse the parts, produce inflammations, abscesses and frightful pains, which frequently end only in death. To the numerous facts which are already contained in authors, we could, without the slightest difficulty, add a multitude of others. MM. Gilbert and Corby, (*Arch. Gén. de Méd.*, t. XVII., p. 139,) Murat, Bard, &c., have also added many to the list, and practitioners daily encounter new instances. The aorta was in this manner perforated in the cases mentioned by MM. Laurencin and Léger or Martin, by a piece of six livres. It was the pulmonary artery in the patient of M. Bernest, and the trachea in the case of Dupuytren, (Bégin, *Journ. Hebdom.*, t. II., pp. 93—124.) Routier, (*Bull. de la Fac.*, t. IV., p. 499,) speaks of a five franc piece which having become implanted in this manner, caused death at the expiration of a month. Dumortier has in this manner seen the presence of a piece of money arrested in the

œsophagus cause a perforation of the primitive carotid artery. When it is evident that the presence of these foreign bodies may produce injury, and that the organism alone is incapable of relieving itself of them, three classes of resources may be had recourse to before proceeding to the section of the œsophagus. They are to be pushed down into the stomach, or obliged to return by the natural passages, or we restrict ourselves to preventing, or combatting even with active means, the accidents they may give rise to should they already exist.

### § I.—*Propulsion.*

We should force into the stomach only those foreign bodies which would be attended with too much difficulty to extract by the mouth, but which having been once got out of the œsophagus will be somewhat less dangerous to the patient. Water swallowed in large quantities, large mouthfuls of the crumb of bread, beef, biscuit, or figs turned inside out, prunes deprived of their pit, portions of sponge with a thread fastened to them, long bougies besmeared with oil, a leek, slight strokes upon the back with the fist, as recommended by De la Motte, and which common people rarely fail to have recourse to, together with I do not know how many other remedies, have been proposed and successively employed in practice with more or less decided advantage, and frequently also without any kind of benefit. In such cases the leaden rod of Albucasis and Rhazes, a ball of the same metal melted and attached to the extremity of a rod of iron, silver or brass, and which was so much eulogized by Mesnier, the silver rod of Verduc terminated in an olive point, and the curved sound, &c., are far also from being always attended with success. In all these I see only the stalk of the leek, which has been quite generally employed since the time of M. Paré, and the leaden ball, which are really worthy of any confidence. It will also be necessary that those two kinds of means should be supported by flexible rods capable of following without difficulty the tortuous shape of the mouth, pharynx and œsophagus, while possessing at the same time a sufficient degree of solidity not to break during the operation.

### § II.—*Extraction.*

When we cannot reach the foreign bodies lodged in the pharynx or œsophagus by means of the fingers, we must have recourse to a long forceps slightly curved, or for example to the urethral forceps of Ravaton, erroneously denominated Hunter's forceps. The species of tenaculum or hook of iron wire of Riviere, (Bonet, *Corps de Méd.*, t. IV., p. 150,) or Perrotin, incurs the risk of lacerating the tissues when it is withdrawn, as occurred to Petit of Nevers. Stedman, by terminating it with a button, has evidently improved this instrument, and Dupuytren, who replaces it by a long silver stem terminated in a ball at one end and a ring at the other, and who makes it an exploring instrument or species of catheter in straightening it, and a hook in curving it, has rendered it still more easy of management.

A. F. de Hilden's hook, in the form of a scraper, would be much more dangerous. That which Petit contrived, with a double flexible silver wire, turned into a spiral form, and curved towards its noose,

in the manner of Pellier's palpebral elevator, has no objection to it but its want of strength. The probe or whalebone having upon it a collection of small movable rings, which was extolled by the same practitioner, and which De la Faye modified by restricting himself to the use of strands of flax attached to the small ring of the common stilette of the catheter, is also not to be neglected, when the body to be extracted is irregular and of small size.

B. A noose of packthread or whipcord, which Mauchart found reason to be satisfied with;—1st, a sponge strongly bound with a thread, and introduced below the foreign body by means of a large leaden canula, at the end of which it is held, and drawing on the two extremities of the thread, which are brought, one through the canal and the other along the outer side of the instrument, as was done by Brouilliard; 2d, the same substance attached to the extremity of a whalebone, as Willis recommends, or of an ordinary catheter, or that leaden, or copper, or cribbled canula, borrowed from Arculanus or Ryff, and modified by Hilden, who, in order to render it stronger, added to it a leaden stylet; 3d, the sponge in addition, which Hévin recommends, should be surmounted by a purse of cannepin or silk, in order to prevent it from swelling before it had descended sufficiently low down, which Bonfils, (*Arch. Gén. de Méd.*, t. XXIII., p. 530,) as well as Petit, attaches to the extremity of a whalebone, inclosed as far up as to its handle in a flexible tube, made of silver wire, rolled in a spiral manner, and which Quesnay covered with sheep-gut, and Ollenroth hung to the extremity of a chain chaplet, composed of 61 balls of pewter, might also be applicable in certain cases; 4th, the same remark applies to the species of broom, whip, or brush, or *excusia ventriculi*, which had already been mentioned by Wedel, Teichmeyer, and Heister, and which the English, who call it *provendor*, form by attaching small portions of scraped linen, or a bunch of hog's bristles, at the extremity of a whalebone, or brass lateen or wire.

C. The manner of using these different instruments, whether for the purpose of forcing the bodies in question into the stomach or for extracting them, is moreover too easily comprehended to make it necessary to dwell any longer upon it. The same remark may be made of their relative value in the different cases where many of them may be advantageous. It is for the skillful surgeon to select which of them is best, the most simple, certain and least injurious among those which he has at command. The species of forceps with several branches, which is opened and closed by a particular mechanism, before and after having seized the foreign body, and which M. Missoux in his thesis in 1825 has described under the name *gerano-rhinque*, is, though ingenious, too complicated to be adopted. The crane-beak, designed for seizing the foreign body while another curved forceps widens the walls of the canal, employed by M. Gen-soul (*Journ. des Hôp. de Lyon*, t. I., p. 233) to extract a piece of cutlet, would be preferable. That which M. Blondeau (*Thèse*, No. 44, Paris, 1830) proposes, and which is founded on the principle of litholabes and enclosed in a flexible sheath, would be equally preferable if it was not already in itself too complex. The same must be said of the ingenious apparatus devised by M. Parant (*Trans. Méd.*

t. VI., p. 72.) The small dilating blade of M. Doussault, (*Thèse*, No. 41, Paris, 1831,) and all those instruments which, after being introduced shut up, open themselves in the œsophagus in the manner of an umbrella, are too dangerous not to be replaced by the bladder that M. Oury (*Thèse*, No. 290, Paris, 1833) attaches to the end of a sound, and does not dilate until after it has been made to advance below the foreign body, should that have presented sufficient resistance to require it.

### § III.

*The efforts of expulsion and vomiting*, which many authors have advised, should be encouraged, notwithstanding the objections of B. Bell, whether they consist in titillating the uvula or the bottom of the throat, or in gorging the patient with warm water, or by any other mode, form a last resource, to which we ought not to resort except for bodies destitute of any asperities or projections, or until after having made use of the two kinds of modes above indicated, and in order only not to have occasion to reproach ourselves for having proceeded too hastily or without necessity to œsophagotomy.

## ARTICLE IV.—ŒSOPHAGOTOMY.

Though this operation may not have been formerly proposed by any person before Verduc and Guattani, it is impossible nevertheless not to perceive that the idea of it is found in several authors who are more ancient. The incision into an abscess containing a small bone which had escaped from the œsophagus and approximated to the integuments of the neck, which had already been performed by Arculanus and Plater; the fish bones extracted in the same manner by Houlier and Glandorp; and the opening into tumors more or less dense or voluminous, which had become developed upon the same region, as practised by Kerkring, Rivals, &c., would naturally lead to this operation. But wounds of the œsophagus had, up to that period, been considered so dangerous that practitioners required numerous facts and direct proofs to dissipate their fears and scruples.

### § I.

*The incision of the œsophagus*, performed for the first time by Goursault in 1738, and then by Roland, (*Acad. de Chir.*, t. III., p. 10, in 8vo, 1819,) is an operation which is applicable only to two descriptions of particular cases: 1st, when we wish to extract a foreign body which, by its presence in the œsophagus, compromises to a greater or lesser degree the life of the patient; 2d, to introduce artificially nutritive substances into the digestive passages, and to prolong to a greater or less length of time the life of those persons who are prevented from swallowing by means of a coarctation of the lower part of the pharynx. In the first case, before proceeding to œsophagotomy, we must make trial of every means in order to compel the foreign body to be ejected by the natural passages, unless it is of such a nature as to render it improper to force it towards the stomach without some danger. Since œsophagotomy has taken

rank among the systematized operations of surgery, it has received, like almost all the others, various degrees of improvement. Guattani, who was not unaware that the œsophagus is situated a little more to the left than to the right of the trachea, advises that we should take up a transverse fold of the skin and incise it from a line with the cricoid cartilage as far down as to the sternum and upon the left side of the neck; separate the lips of the wound by means of hooks; and arrive gradually to the œsophagus, and divide it in a direction parallel with its fibres. According to B. Bell there can be no settled place for the incision, as it should always be performed upon the projection which is made by the foreign body. He knew moreover that with certain precautions the recurrent nerve could easily be avoided.

To be more certain of dividing no vessel of any size, Richter recommends that the muscles should be separated by means of an ivory knife. The method of Eckholdt, extolled for what reason I do not know, by Sprengel, and which consists in making the external incision fall upon the triangular space which separates the two roots of the sterno-mastoid muscle, appears to me to deserve the oblivion into which it has sunk. I would make the same remark of that of V. Gescher, (*Rust's Handbuch der Chir.*, t. XII., p. 281,) who recommends that we should traverse the trachea to reach the œsophagus from before backwards. M. Chas. Bell says, that if we place the thumb on the track of the internal jugular vein, in order to cause it to distend while we are incising the skin, the platysma-myoïdes and nervous branches of the cervical plexus, and that if we separate the muscles apart by means of the handle of a scalpel, the œsophagus will soon present itself, so to speak, of its own accord, and that in this manner, œsophagotomy is not dangerous; but this author is evidently mistaken in regard to the importance of a precaution of this kind. M. Richerand, who only admits of œsophagotomy in cases where the size of the foreign body is so considerable as to make a protrusion beyond the surrounding parts, and who justly maintains that it is almost always at the entrance of the canal of deglutition that these bodies become arrested, adopts, in every particular, the process of Guattani or B. Bell. In this hypothesis, in fact, the external projection is a guide which directs with certainty to the œsophagus, and which favors the pushing aside of all those organs which it is important should be avoided. An instrument which was devised by Vacca enables us to effect the same object in all cases. It is a long metallic stem, terminated in a button, and cleft in the form of forceps at one of its extremities. This stem slides in a canula, which has a large opening upon one of its sides at some inches beyond its extremity. The complete instrument is introduced, shut up, until it reaches to below the foreign body. The surgeon then draws gently towards him the forceps, one of the branches of which, acted upon by its own elasticity, does not fail to get caught in the lateral hole of the canula, which served it as a sheath, and thus raises upon the side of the neck the different layers which are to be divided. But the dart-shaped sound is infinitely more convenient still than the instrument of Vacca, if it be that we require a director when we perform œsophagotomy. In raising up all the soft parts to the left, and in front, by means of the beak of a sound, previously introduced

nearly down to the body to be extracted, as proposed by M. Roux, the carotid artery, jugular vein, and pneumo-gastric nerve are necessarily left posteriorly. The thyroid vessels themselves, and the trachea, are also sufficiently distant to prevent any danger in pushing his dart-shaped instrument from within outwards, and from making use of it afterwards in the manner of a canulated sound, as in lithotomy. Nevertheless it is unnecessary to proceed in this manner blindfolded. Nothing prevents our dividing at first, layer by layer, the different tissues which separate the œsophagus from the integuments, and not making use of the sound except in the last stage of the operation. By this process œsophagotomy has no longer any thing alarming in it, or difficult, and may be performed by every surgeon. If it were necessary, in fact, there would be no objection in substituting an ordinary sound for that of F. Côme.

## § II.—*Operative Process.*

The patient is placed in the same way as for tracheotomy, except that we incline his face a little towards the right. The surgeon, standing up, and to the left, divides with a straight bistoury the integuments and platysma-myoides, to the extent of two or three inches, upon the anterior border of the sterno-mastoid muscle, between the sternum and the larynx, and as much as possible immediately opposite to the foreign body, the position of which he has previously ascertained, by means of the blunt-pointed sound of Dupuytren, the dart sound, or any other instrument. Afterwards pushing this muscle towards the outside, he lays bare the omo-hyoid and sterno-hyoideus; pushes them aside in their turn; tears, by means of the beak of a canulated sound, or cautiously divides with the bistoury the fibro-cellular layers, in the same way as if he were applying a ligature to the primitive carotid artery; then raises up and pushes inwards and forwards the thyroid body. Adopting the same precautions until he comes down to the groove, which is situated laterally between the œsophagus and trachea, he there encounters the inferior laryngeal nerve.

Having introduced his dart sound through the mouth, he causes its point to pass through the œsophagus, as far down as to the bottom of the wound; secures it with the thumb and left forefinger; requests an assistant to push forward its arrow; directs the point of his bistoury upon the grooved concavity of this stem, and immediately makes an incision into the œsophagus, proportionate to the size of the body to be extracted. When we do not employ a director, we must first open into the canal on its side by a small puncture, which enables us immediately to introduce a canulated sound into its interior, and afterwards to enlarge its wound by means of a bistoury or blunt-pointed scissors. If the substance to be removed does not present itself at the opening which has just been made, we must proceed to search for it by means of forceps or any other appropriate instrument. The wound may be united by first intention. If an arterial branch of some size has been wounded, a ligature is to be applied to it. A gum-elastic catheter must be introduced through the nares or mouth, as far down as into the stomach, and not be withdrawn from it before

the third or fourth day, in order that the aliments and drinks may not in any manner interfere with the agglutination of the wound of the œsophagus, or escape into the tissues of the infra-hyoid region. If œsophogotomy, performed on the thirtieth day by M. Arnott, (*Gaz. Méd.*, 1834, p. 45—*Med. Chir. Rev.*, July, 1833, p. 210.) to extract a portion of the vertebra of a sheep, caused the death of the patient at the expiration of three days, two patients that were operated upon after these precepts at the Val-de-Grâce by M. Bégin, (*Journ. Hebd.*, t. XI., pp. 94, 111, 124,) one on the eleventh day, and the other on the sixth, in order to extract a piece of bone, were perfectly restored.

### § III.

*The anomaly pointed out by MM. Steadman, Kirby, Hart, Godeman, and Robert, as well as by myself, of a carotid or subclavian passing around the œsophagus in the manner of a spiral, or gliding under its vertebral surface in order to reach the side of the neck, would not expose to any dangers unless the operation should be performed very low down.*

[An *iron-cellar key* four inches long and one in breadth at either extremity, got lodged in the upper part of the œsophagus, and there remained for the space of 58 days, giving rise to the supposition only of a protracted tracheo-bronchitis, wasting away the strength, and not materially interfering with the swallowing even of hard solid food. This occurred in the case of a woman aged 42, described by Dr. R. Jackson of Leith, (*Edinb. Med. and Surg. Journ.*, July, 1843,) the woman having designedly swallowed the key to destroy herself, yet persisting in denying it to her death. The block of the key was found resting close to the epiglottis and on the hyoid bone, the shank of the key and ring lying downwards in the œsophagus, the ring having caught in a fold of the lining membrane of this tube, and which fold constituted a sac for it. Some thickening of the tube was apparent, and a few slight ulcerations. Death was here caused by irritation of the air-passages, not by dysphagia.

Dr. Antony of Philadelphia, (*Philadelphia Med. Examiner*, April, 1845,) ingeniously removed a fish-hook lodged in the gullet, (and which a boy had mischievously dropped with its line into the throat of an old lady while she was asleep,) by saving a portion of the line, and passing down by this means upon the hook a bullet drilled through the middle. Then passing down upon this bullet by means of the same string a hollow reed, the hook and bullet were withdrawn through the reed without any injury to the parts.

*Foreign Bodies in the Integuments, Eye, &c.*—Dr. Bachelder of this city, (see Collins's *New York Medical and Surgical Reporter*, June 27, 1846, p. 303, &c.) in cases of *needles, &c. in the palms of the hands and soles of the feet*, operates with great success in the following manner :

“The operation to which I allude, and which, as I have said before and now repeat with emphasis, I have practised with uniform success, is to make two incisions, which commence in a point a little distance, say a quarter of an inch, from the place where the needle

entered, and diverging on either side of the place of entry, and dissect up the triangular flap, whose base and sides should be about five-eighths of an inch long. It is best that the point whence they diverge should be longitudinally in a line with the place of entry, and on the proximal or distal side of it, according to the supposed direction in which the needle entered or lies. These incisions, which should of course correspond as nearly as circumstances will admit, with the longitudinal direction of the member, may be carried down to the palmar or plantar aponeurosis, and indeed through either if necessary, with safety; for the blood-vessels and nerves lie beneath those membranes: and the dread of wounding the fibrous tissues of these parts has long since ceased to haunt the imagination of the surgeon. As the resistance of those aponeuroses causes the fracture of the needle in most instances, to happen just exterior to them, you will generally need only to dissect and turn back the triangular flap of integument, and then if requisite, remove with the dissecting forceps and scissors the cellular substance which intervenes between it and the aponeurosis, in order to feel and extract the foreign body with the fingers or forceps. If you do not succeed, the aponeurosis itself may be treated in the same manner as the tegumentary covering.

“As needles and pins have remained many years in the system—have travelled in all directions, and been found in almost every part except the brain, without having caused much harm or serious inconvenience, the question might be asked whether it is best to interfere at all, or let them remain and take their own course; to this interrogatory I would reply, that I have also known many cases in which they were productive of very serious mischief, by undermining the general health, and nearly, if not quite depriving the patient of the use of the limb; therefore always remove them in the first instance if practicable.”

M. Castelnau (*Arch. Gén.*, 3e ser., t. XV., p. 210, &c.,) relates the extraordinary case of a man, who for three years and a half retained a sharp, triangular fragment of iron, 13 millimetres in length, in the globe of the eye, without producing any other effects than severe pains in the organ, but not until two years after the injury occurred. It then made its way, but *without* any *suppuration*, to the cornea, where it occasioned intense conjunctivitis. It was readily extracted, when the accidents immediately ceased. The absence of the suppurative process noticed by M. Velpeau in the text, as the usual consequence of metallic fragments in the globe, is, when taken into connection with the unprecedented size of the foreign body, and its comparative innocuousness for so long a period, a remarkable feature in this case. T.]

## PART THIRD.

## THE CHEST.

## CHAPTER I.

## TUMORS.

## ARTICLE I.—TUMORS AND EXTIRPATION OF THE BREAST.

§ I.—*Indications.*

A. *Compression*, employed from 1809 to 1816 by Yonge, rejected as dangerous in 1817 by the physicians of Middlesex, upon the report of Chas. Bell, and proposed at a subsequent period by Pearson, has since afforded to M. Récamier results which this practitioner considers worthy of attracting attention in treatment of tumors of the breast. Nevertheless this is not a reason for rejecting the operation properly so called, or for not recurring to it but as an extreme measure as some people seem to think. Many women cannot support compression, however well it may be made. A great number of cases obstinately resist its application, and nothing proves that it has ever *cured a true cancer*. Under the most fortunate circumstances, the assiduous cares that it exacts are so fatiguing in themselves, as to have given rise to the question, if extirpation be not preferable to it. It is not, in fact, as an operation, that extirpation of the breast is dangerous, but because it is frequently followed by a return. The amount of pain that it produces is assuredly less than that which results from a course of treatment whose duration cannot be less than from two to three months. In an instant the patient is relieved of her disease, and fifteen days or a month ordinarily suffice to effect a complete cure. On the other hand there is no reason for maintaining that the return would be less frequent after the employment of the compressing bandage, than after the ablation of the scirrhus. Experience has already shown that when it becomes necessary to suspend the compression, before having entirely dispersed the morbid mass, the progress of the cancer soon goes on with an increased rapidity, in such manner that its development, though momentarily arrested, soon assumes a more frightful character than ever.

B. As to the question whether *extirpation is a remedy* which sound practice ought to allow us to make trial of, I do not hesitate to answer in the affirmative. To Celsus, (Sprengel, t. VIII., trad. Franc., p. 422 ; Celsus, liv. V., chap. xviii., sect. 2,) who forbids the cancer from being meddled with, because it always returns ; to Albucasis, (*Chir.*, lib. II., s. 53 ; Sprengel, VIII., 487,) who has never seen the operation followed by entire success ; to Monro, (Sprengel, VIII., 457,) who says that out of more than sixty women whom he had met with, after this operation, four only had not had a return at the expiration of two years ; to Boyer, also, (*Mal. Chir.*, t. VII., p.

237,) who, out of more than one hundred cases, could cite only a very small number of radical cures; to Rouzet, (*Rech. et Obs. sur le Cancer*, 1829,) who asserts that he has found in the annals of science but very equivocal evidence of permanent success; and to M. McFarlane, who, out of one hundred cases, has not seen one effectual cure; we may oppose the evidence of Hill, (*Cases in Surgery*, Edinburgh, 1772,) who, out of eighty-eight extirpations, most of which were ulcerated, has met with but twelve failures; that of Schmucker, (*Bibliot. Chir. du Nord*, p. 296,) who operated at the beginning of the disease; that of B. Bell, who confirms the accuracy of Dr. Hill; and that of Dr. North, quoted by Dorsey, (*Elements of Surg., &c.*, vol. II., p. 4,) and who, out of one hundred examples, noticed but a very small proportion of a return of the disease. MM. Richerand, Roux and Dupuytren, and before them Sabatier, on their part, had evidence that cancer is far from repullulating always, when the extirpation has been made in time. My experience also shows that many patients operated upon at Tours by M. Gouraud, at the hospital of St. Louis by M. J. Cloquet, and at the hospital of the School of Medicine by MM. Bougon and Roux or myself, since the last 12, 8, 6, 4 and 2 years, continue to enjoy good health.

C. *Cancer* of the breast is not the *external sign of a general disease*, as Delpach maintains, at least in most cases, except at quite an advanced period of its development. In the majority of cases, it is at first only a local affection, but one which tends constantly to pervert the fluids and solids to such extent as to be soon reproduced on one region or another, although it may have been entirely destroyed at the part where it appeared to be situated.

Consequently nothing can be more dangerous than to shrink from its ablation under idle pretexes; and compression, which is necessarily less efficacious, would not be proper to be had recourse to, except in timid persons, or such as from any cause whatever were not willing to submit to the action of the bistoury. If general and local treatment possess any value, the operation, which is in no respect incompatible with their employment, cannot but favor their success. We should be wrong even to allow ourselves to be deceived by the presence of certain glands at the hollow of the axilla or in the supra-clavicular region. These glands may have preceded the scirrhus, or been produced by it without participating in its character. Bartholin, Borrich, Assalini and Desault, (Sprengel, *Hist. de la Méd.*, t. VIII., pp. 439, 440,) have seen them disappear spontaneously after extirpation of the cancerous breast. The same fact has been frequently noticed in these latter times. This result took place in 1825, in a woman operated upon by M. Roux, at the Hospital of Perfectionnement, and who had a chaplet of indurated glands extending from the side of the neck down into the hollow of the axilla. Nor does a slight yellowish tint, or the commencement of what is called the cancerous diathesis, always form an absolute counter-indication. Morgagni, having to treat a patient in this condition, ventured to extirpate in spite of the formal advice of Valsalva. The cancer returned at the end of five years; Morgagni again operated and the disease was not reproduced. The adhesions of the tumor to the ribs considerably diminish the chances of success, but do not render it absolutely impossi-

ble. The operation therefore should be performed in all cases where the last roots of the disease may be extirpated without occasioning too great a loss of substance, and where there is no evidence to show that it exists in the other organs.

## § II.—Operative Processes.

It is to the barbarous processes used at different epochs by various surgeons, that we must look for an explanation, if the removal of the breast still occasions so much alarm to people in general.

A. Cauterization of the wound with the iron heated to a moderate red heat, already mentioned in the writings of Galen; the precept of Leonidas, (Aetius, tetr. 4, serm. 4, cap. 43; Sprengel, 8, 423,) to burn after each cut of the bistoury the bottom of the wound in order to prevent hemorrhage; or excision with the knife heated to a white heat, or when the cancer is adherent, by means of a blade of horn which has been dipped in aqua fortis, as prescribed by J. Fabricius, (*Op. Chir.*, p. 1, cap. 49; *Op.*, 196; Sprengel, 8, 436,) must necessarily have been attended with excruciating pain. The process of Scultetus, (*Arman.*, p. I., p. 22, tab. 24, 36; Sprengel, 8, 441,) which consisted in introducing *two threads crosswise* through the tumor, in order to raise it up and excise it with a single cut of a large concave bistoury, and then to cauterize the entire bleeding surface with a plate of red hot iron; that of Purmann, (*Chir. &c.*, t. II., chap. 6, p. 144; Sprengel, 8, 444,) who added to these threads a ligature *strongly tightened* upon the root of the disease with the view of benumbing the parts; those of Nuck, (*Obs. et Exper. Chir.*, p. 101; Sprengel, 8, 445,) who used *a double hook* and a falciform knife; of Dionis, (*Oper. de Chir.*, demonst. XI., fig. 28,) who commenced by plunging into the cancerous mass those famous *Helvetian forceps* of which so much was said at the commencement of the last century; of Hartmann, (Barbeau, *Thèse de Haller*, t. I.,) and Vylhorne, (*De Cancro. Mam.*, &c.; Haller, 2, 449; Sprengel, 8, 453,) who after having strangulated the schirrus at its base, secured it still farther by means of a sort of *veterinary pincers*, (moraille,) and then with the *bident* of Helvetius, while its excision was effected by a mechanical instrument of their invention; and of Schmucker, (*Chir.*, &c., lib. II., p. 51; Sprengel, 8, 471,) who after having laid open the skin pressed the tumor in order to make it protrude, introduced into it a species of *awl slightly curved*, and then separated it from the surrounding parts; were also well calculated to create such apprehensions.

B. Those who caused the separation of the tumor by surrounding it with a *ligature saturated with aqua fortis*, or who having entirely or partially excised it in one way or another, made use of the repeated applications of arsenic, orpiment, potash, butter of antimony, &c.; and those who cautiously dissected all the surrounding vessels, in order to place a double ligature on each of them, and to divide them without danger in the interspace of the two threads before removing the cancer, or who after the incision of the integuments made use only of their fingers, and terminated the operation by tear-

ing out the tumor, presented no arguments for changing public opinion upon this subject.

C. At the present day, when *extirpation of the breast* is reduced to its greatest simplicity, there is nothing in it which is alarming or in reality severe.

I. *When the skin is in no respect diseased*, nor the tumor of a large size or adherent, the surgeon confines himself to dividing the common integuments, taking care to give to the incision all the extent required, and to cause its lips to be separated apart, while with an erigne, or even with the ends of his fingers, he draws the scirrhus to the exterior, and with the other hand armed with a bistoury, destroys all its cellular or vascular attachments. When the patient possesses a certain degree of embonpoint, or that the breasts are naturally greatly developed, though the carcinoma may be clearly circumscribed and preserve all its mobility, there is some advantage in not being so sparing of the skin, and in excising even an ellipse from it of greater or lesser extent. The operation is thus rendered more easy and more prompt. Its success also then becomes more probable, for the lips of the wound, which are then moreover cut almost in a uniform manner, are placed under more favorable conditions for exact coaptation, than if all the integuments had been preserved.

II. *If the skin itself is comprised* in the disorganization, or red, or too attenuated ever to acquire its primitive characters; or if it adheres by its deep-seated surface to the morbid mass, we are still compelled to adopt the same precept, and to include the entire diseased portion between two incisions, which should always embrace a certain extent of sound parts, that is, between two semilunar incisions, as recommended by Zeller and Kern, (*Rust. Handb. de Chir.*, vol. VI.) In conclusion, it is much better to remove more than less, provided we leave enough to allow of reunion of the wound by first intention. The circular incision adopted by the ancients, and also by Dionis, is essentially objectionable. It makes a wound which is difficult of cicatrization, and the loss of substance which it produces is much more considerable than by any other mode. It can be applicable only to globular tumors, which are as it were confounded with the skin upon their anterior surface. It would be under such circumstances, that we might, after the example of M. Fardeau, (*Journ. Hebd.*, 1835, t. IV., p. 110.) by means of a knife introduced through the tissues between them and the chest, detach the tumor first above and then below. The elliptical incision which was already used by Paul of Egina, (Sprengel, t. VIII., p. 425,) and afterwards by Cheselden, (*Observ.*, &c., 1749; Sprengel, t. VIII., p. 452,) &c., is the most convenient of all. The crucial incision preferred by Palfin (Sprengel, t. VIII., p. 450.) and Heister, (*Institut. Chir.*, Sprengel, t. VIII., p. 451;) and the T incision employed by Acrel, and even by Chopart, (Sprengel, t. VIII., p. 475,) evidently possesses fewer advantages, and would be applicable only in certain particular cases.

D. Some with Gahrlied and M. C. Bell, place the great *diameter of this incision* from above downwards; others prefer that it should be transverse; while the precept of Pimpernelle, recommended according to Sprengel by Verduc, and which consists in placing it obliquely from above downwards, and from without inwards; that is

to say, in the direction of the fibres of the pectoralis major, is generally adopted by the moderns. The advantage of being enabled to apply the uniting means with more facility in the first case, is more than counterbalanced by the risk of dividing the muscular fibres perpendicularly, and of not being enabled to bring to the outside the sternal portion of the integuments but with much difficulty. The second process would incur the risk of the same inconveniences, without which enables us to employ the adhesive straps, as well as any other presenting the same advantages. Consequently the oblique incision, process, and which leaves intact the fibres of the pectoralis major, deserves the preference which is now accorded to it.

E. In a case of necessity, all *cutting instruments* are applicable to this operation. We could, if so disposed, succeed with a razor or amputating knife. The bistoury, with a broad and square-shaped point, devised by A. Dubois with a view of avoiding the chest with greater certainty, is neither better nor worse than any other. The ordinary straight bistoury, or better still the convex, is the one which is usually employed. In order that the blood of the first incision may not interfere with the execution of the second, we begin in conformity with the indication laid down by Palfin, and afterwards by Desault, by the lowest. Nevertheless, when the section of the integuments has been once effected, there is some advantage in dissecting the tumor from above downwards. In the opposite direction the lower or outer border of the pectoralis major would be much more exposed to the action of the bistoury. No one moreover at the present day recommends with Horne, (Sprengel, *Hist. de la Méd.*, t. VIII., p. 440,) Lapeyronie. (*Ibid.*, 463.) and Le Dran, (*Opérations*, p. 375,) that we should commence by a semilunar incision, and not complete the ellipse which is to represent the wound until after having detached the cancer always in the same direction, or, terminate by dividing the skin from the deep-seated parts towards the exterior, as recommended by M. Galenzowski. This manner of proceeding however has no other defect than that of giving less regularity to the termination of the operation, and of incurring the risk of destroying too great or too small an extent of the cutaneous tissue.

F. *When the loss of substance is considerable*, and to so great an extent as to render the coaptation of the borders of the division impossible, or at least very difficult, it has been proposed to isolate each lip of the wound from the subjacent parts, to the distance of one or several inches, hoping by that means to remove all the obstacles which are opposed to their approximation. This is a modification, the value of which, in my opinion, has not hitherto been fully appreciated. By means of this process we should always have a sufficiency of skin to unite the wound by first intention; the integuments are then borrowed from the surrounding parts, and the process must always be a precious resource in cases where we have been compelled to destroy a large portion of the cutaneous envelope. Under the chapter on anaplasty, I have stated what value ought to be placed under such circumstances upon the different descriptions of autoplasty, and especially of the process that M. Martinet (*Gaz. Méd.*, 1834, p. 657) appears to have employed.

G. *The small arteries* that are divided belong to the external

mammary, the superior thoracic, the internal mammary or the intercostal arteries. Those that we meet of the largest size, and which we must first attend to, are always towards the outside. In placing a ligature upon them in proportion as we divide them, there is no danger that they will retract and escape into the midst of the tissues, nor that the action of the air will prevent our finding them again subsequently; but the operation in this way becomes more laborious and protracted. Unless they should be too numerous or very large, I prefer making use of the fingers of an assistant to close their orifices at the moment that they are divided by the bistoury. Should there be any which cannot be found after having cleansed the wound, they are generally too small to occasion the slightest inquietude. In the contrary case, it would be so easy to establish upon them a point for indirect or direct compression, that in this respect we have in reality but little to apprehend. Even when we unite by first intention, ligatures are far from being always indispensable. Theden did not make use of them; and Petit ordinarily dispensed with them. D'Arce and Vanhorne, who also omitted them, tore out the tumor with the fingers, and only used the bistoury for dividing the integuments. I have frequently dispensed with them, and among other cases, in that of a young woman in whom I had removed a scirrhus mass as large as the fist. Prudence, however, requires that we should tie or twist all those which may be recognized; and that if there be any that escape the researches of the surgeon, the dressing should be carefully watched during the space of a day or two.

H. The precaution of not *definitively dressing the wound* until after the expiration of some hours, in order to give time for the centrifugal action of the vascular system to become established, and to make manifest the arterial mouths which are to be closed, would possess the serious inconvenience of worrying and tormenting many patients, and of being at the least unnecessary. At the present day it would be absurd and barbarous to dissect, as has been recommended, and afterwards to excise all the veins that go to the breast, or only to compress or agglomerate (*masser*) them by means of the fingers, in order to extract or expel from them that black or atrabiliary humor which the ancients had so much dread of.

I. *Immediate union*, which was indicated by Paul and Gahrlied, and lauded by Nannoni, who confined himself to approximating the lips of the wound, and also by Cheselden and Garengot, who employ the suture, and which has been adopted by almost all the moderns, nevertheless finds some opponents. The objection made to it is that it interferes with the issue of any matters that may form at the bottom of the wound, and of being frequently followed by phlegmonous erysipelas, and consequently that it may jeopardize the success of the operation. These formidable accidents, especially in fat or cachectic women, will be in most cases avoided, if no void is left at the bottom of the wound, if the coaptation is more exact near the muscles than towards the skin, and if the containing means act principally upon the deep-seated parts, and not exclusively upon the cutaneous tissue; if in a word we take care to reserve an opening at a depending part for the escape of the fluids. Moreover, as it is almost next to impossible to obtain perfect primitive reunion, perhaps

it would be more prudent to treat the wound by secondary immediate union. As to the suture, though again warmly recommended by M. Serre, I should not venture to recommend its employment in these cases, until after having seen results from it more fortunate or more conclusive than those which it has given me up to the present time. It evidently renders the operation more painful. Except in certain cases, where the skin is so attenuated that after being dissected it has a tendency to roll up upon itself, adhesive plasters, or the simple bandage, may be perfectly well substituted for it. M. Chaumet, (*Journ. des Conn. Méd.-Chir.*, t. V., p. 117,) who gives three examples of it and eulogizes it, says that the cure in his first patient was effected in 52 days, in 15 days in the second, and in one month in the third; but since without its employment we may, in reality, accomplish the cure in the space of ten to twenty days, I cannot see what advantages it would possess.

### § III.—Operative Process.

Though we may, as many practitioners do, support the patient on a chair while we are operating upon her, there are nevertheless indisputable advantages in placing her in a recumbent posture, either upon the bed or upon an operating table. The syncope is then much less to be apprehended, and the surgeon is in fact much more at his ease. The head and chest are to be sufficiently elevated, to make the breast project as much as possible. The pelote which Bidloo directed to be placed in the axilla, in order to push the breast forward while the arm was directed backwards, would not deserve to be mentioned, if M. S. Cooper had not recommended a precaution which is somewhat analogous and not less curious: he advises that, in order to keep the arm separated from the trunk, to command the movements of the patient, and to force the pectoralis major to become stretched, a baton should be fixed upon each side in the hollow of the axilla, between the chest and the limb!

A. A second assistant *raises up the tumor* with one hand, and with the other sponges up the blood in proportion as it runs out. The surgeon makes traction upon the skin in an opposite direction; commences with the lower semilunar incision; then depresses the mass to be removed and stretches the integuments above; applies the bistoury to the outer angle of the first wound; and makes the upper incision by conducting it to the other extremity of the lower division, and in this manner completes his ellipse. He then seizes the scirrhus or causes it to be grasped, dissects it freely, first from below upwards and then from above downwards; proceeds in such manner that the tumor may continue surrounded by a margin of sound tissues and not be elevated exclusively; cuts down to, or ought not to fear cutting down to, the muscular fibres, and even as far as to the ribs of the thorax, should the extent of the disease require it.

B. If, as I prefer, unless there should be large arteries *that they should not be tied*, the surgeon directs them to be closed with the finger in proportion as the bistoury divides them, and may in this manner terminate in a few seconds the ablation of a breast of the largest volume. Upon the supposition that some morbid layers or

peletons have at first escaped the instrument, we must afterwards return to them without delay. When they belong to the soft parts, they are to be excised by the bistoury or the scissors, and should the bones be affected, the rasp might become necessary. Having arrived at this point we should not even hesitate to exsect one or more portions of the ribs, should it appear that their removal would enable us to destroy all the parts diseased; but if before commencing, this change had been indicated by any sign, it would in my opinion be much better not to undertake the operation.

C. *If there should be found in the arm-pit, glands* which create some apprehension, they are when not too remote to be laid bare by prolonging over them the external angle of the wound. In the contrary case it is better to cut down to them by means of incisions independent of the first. Their position, which is calculated to produce some alarm at first view, nevertheless allows of their being extirpated in almost every case without the slightest danger. They are in fact almost always constantly found upon the outer surface of the serratus magnus, so that in order to separate the brachial plexus from them, we have only to raise up the arm and to hold it at a slight distance from the trunk. Nothing moreover is easier, when we are under an apprehension of wounding any vessels of considerable size, than to embrace their pedicle with a ligature after having isolated them in a proper manner, and then to excise them external to the thread. This practice, which had already been recommended by J. L. Petit and Desault, and which Zang and Dupuytren adopt, deserves to be retained. As to the division of the veins it is rarely alarming in respect to hemorrhage. I have seen the axillary vein itself wounded during an operation of this kind, and tamponing suffice for the effectual arrestation of the effusion of blood.

D. If, after having *cleansed the wound* and the surrounding parts, the operator is desirous of attempting immediate reunion, he gently approximates the borders of the division and keeps them in contact by means of the thumb and forefinger of each hand, while the assistant applies the adhesive plasters. In general, the longer the adhesive plasters are, the better. Being stretched over a great extent of surface, their action becomes much less irksome at the cutaneous division, while they are kept on infinitely better than if they were short and more numerous. Some persons, however, allege the contrary, and Prof. A. H. Stevens of New York, among them, recommends that they should be as short as possible. It is necessary that they should cross the wound at a right angle. When the loss of substance is considerable, or that it becomes difficult to bring the integuments into coaptation, there is an advantage in attaching them behind the sound shoulder and then bringing them above the clavicle and conducting them to below the axilla or upon the diseased side. We begin with those of the middle and finish with those at either end. Their number should vary according to the extent of the wound, in front of which they are to form a kind of *grillage* sufficiently close. A plumasseau besmeared with cerate, and one or two gateaux of dried lint with long compresses, supported by a body bandage or the circulars of a long band, passed moreover once or twice in the form

of a *quadriga* around the shoulders, complete the dressing, when the patient is immediately removed to his bed.

E. When we cannot, or do not wish to attempt immediate reunion, adhesive plasters are generally of no use. We then surround the wound with bands of linen besmeared with cerate, or we cover it with a fine linen uniformly imbued with ointment and perforated, in order that the lint which is to be placed over this may be easily removed at the first dressing. If afterwards there should appear the slightest vegetation or tubercle of doubtful character, it should be destroyed without hesitation and as quickly as possible, either by the cutting instrument, the red hot iron, zinc paste, or any other caustic, such, for example, as those recommended by La Poterie, F. Côme, A. Dubois, &c. I will add no remark in this place to what I have already said of caustics in the chapter which is devoted to them in this work and under the article on *tumors*. The cancers which present, in this respect, the least hope of success, belong especially to the cerebriform, melanotic and scirrhus tissues. Those which seem to be, and are in fact, prolonged into the surrounding cellular tissue, by a number of divergent radii or roots, are the most formidable of all, and rarely fail to be reproduced; while on the contrary, the extirpation of colloid cancers, and hydatiform, encysted and tuberculous tumors, is quite often followed by a radical cure.

F. If the case is that of a *man*, as in the examples related by Bartholin and MM. Sédillot and Petréquin, and in those which belong to myself, the operation should be nevertheless performed after the same rules. But in cases of cysts, whether milky, like those mentioned by Volpi, (Nelaton, *Thèse*, 1839, p. 48,) M. Cumin, (*Trans. Med. Chir. of Edinburgh*, p. 594,) &c., or sanguineous, or sanguinolent, or serous, purulent, or hydatid, or osseous and mucilaginous, like those which I have elsewhere described, it would be better, unless there should be a considerable number of them, to treat them with injections of iodine or by incision, and even simple excision, than to attempt their extirpation. I have only to refer, moreover, for what relates to the different kinds of tumors of the breast, to what I have said of the processes that are applicable to tumors in general, and also to my special memoir (*Traité des Mal. du Sein.*, Paris, 1838,) upon this subject.

## ARTICLE II.—TUMORS OF THE THORAX DISCONNECTED WITH THE MAMMA.

The cases, first of a hypertrophied mamma weighing sixty-four pounds, observed by Durston, (Nelaton, *Thèse de Conc.*, 1839, p. 5,) another which weighed twenty pounds, as mentioned by M. Kober, (*Ibid.*, p. 7,) the three examples of *gynæcomasty*, noticed in man by M. Bedor, (*Ibid.*, p. 17,) those of osseous tumors described by Morgagni, Bidloo, Wolf and Cooper, of tuberculous masses extirpated by M. Gerdy, (*Ibid.*, pp. 45—47,) of milky calculi encountered in animals by Ruysch and Morgagni, and in man or woman by Rufus, Bassius, Kulm, Morgagni, Dupuytren, (*Ibid.*, p. 59,) &c., will have to be added to those which I myself have related. A vast erectile tumor, which occupied the side of the chest and the hollow of the axilla, was extirpated with success by Maréchal, (*Arch. Gén.*

*de Méd.*, t. XXVIII., p. 149.) Having treated in detail, in the chapter on loupes and other tumors, of tumors upon the thorax and in the axilla, it is unnecessary for me to recur to this subject in this place.

## CHAPTER II.

### EFFUSIONS INTO THE THORAX.

#### ARTICLE I.—EMPYEMA.

##### § I.—*Indications.*

The operation of empyema, performed in the remotest period of antiquity, owes its origin, according to fable, to the despair of Phales or Jason, who, seeking death in the midst of battle, received the thrust of a lance in the chest, and was thus relieved of an empyema, of which no person had ventured to undertake the cure. Galen alleges that in Greece it was performed by plunging a red hot iron through the thorax. At the time of Hippocrates, after having satisfactorily ascertained the existence of a collection, an opening was made into one of the lowest intercostal spaces with the bistoury or a large lancet protected by linen wrapped around it. Others, for fear of evacuating all the liquid too rapidly, perforated the fourth rib by means of a trephine, and then closed up the hole with a plug or tent.

The Arabs appear to have proceeded in the same manner in this respect as the Greeks and Romans. Among both it is perceived that the operation for empyema, first recommended and employed without repugnance by most practitioners, ended in being no longer recommended by any person. Paul of Egina, among the first class, recommends that it should be replaced by cauterization of the thorax, and Haly Abbas, among the second class, formally rejects it. G. de Salicet and Guy de Chauliac speak of it with extreme dread. A. Benedetti, J. de Vigo, and Paré did not succeed but in temporarily rescuing it from the discredit into which it had fallen, and it required all the efforts of J. Fabricius to bring it again into repute; so that it is only in reality during the last two centuries that its advantages and inconveniences have been discussed, and that it has again attracted the attention of surgeons.

A. *Sanguineous Effusions.*—Whether the blood which has accumulated in the pleural cavities proceeds from the intercostal arteries, or from the deeply situated vessels, whether it proceeds from a traumatic lesion, a perforating wound, or a spontaneous laceration, or whether it be arterial or venous, the dangers nevertheless which result from it, and the remedies to be employed for its relief, are nearly the same. The advice that we should immediately proceed to the extraction of the effused liquid, either by placing the patient on the wounded side, by enlarging the wound, or by making use of the mouth, a cupping-glass, or a syringe, to suck out the fluid as it

were with a pump, far from being advantageous, appears on the contrary to be extremely dangerous. Is it not moreover probable, that after the first hours, and until time shall have been given for the blood to become again liquefied, it will be found in part at least in the condition of clots in the chest, and that in such cases it would be impossible to extract it by a puncture? The vessels wounded cannot be obliterated or closed up except by means of clots more or less solid, and a greater or less degree of strong compression. If in place of being retained in the chest, the blood escapes to the outside by this compression, the clots will not be made to form and the hemorrhage will end only in death. Reason therefore instructs us to close up the wounds of the chest immediately at first, in place of dilating them, and to imprison the extravasated blood in the interior instead of procuring an exit for it. If the effusion is inconsiderable, it will generally be removed by absorption; in the contrary case, its source cannot be surpressed but by itself and by the mechanical reaction which it soon exercises against the wounded organs; so that the operation for empyema is under no circumstances proper for recent traumatic hemorrhages of the thorax. Some facts collected in the time of Vigo and Paré, a passage in Francois d'Arce, another in G. Horst, and the remarks of Sharp, and especially of Valentin, would have naturally led to this suggestion; but it was reserved for A. Petit and M. Larrey to have the honor of demonstrating and satisfactorily establishing, that the first indication in perforating (*pénétrantes*) wounds of the chest, whether with or without effusion, is to close them up immediately. If afterwards the system, aided by judicious general treatment, should be found incapable of effecting the dispersion of the morbid collection; or if when the wounded vessels have had time to become obliterated, this collection threatens in itself to give rise to serious accidents, it is then allowable, but only under such circumstances, to have recourse to the operation, and to perform what is denominated a counter opening. The memoir of M. Priou, on wounds of the chest, (*Mém. de l'Acad. Roy. de Méd.*, t. I.) will give the reader every information necessary on the subject of effusions of blood in the thorax.

B. *Effusions of Pus*.—As purulent collections in the chest are far from constituting always the principal disease, the operation for empyema in such cases, in its turn, is far from being always a source of any great benefit. If they have originated from a tuberculous vomica, or any other incurable lesion of the pulmonary organ; if they are the product of a deep-seated alteration still existing in the heart or pleural linings, we should, by giving exit to them, only hasten the death of the patient. If, on the contrary, they have been caused by a simple phlegmasia, or pleurisy for example, or by an abscess in the lung which has made its way into the pleural cavity, the operation presents some chances of success and ought to be made trial of. A vomica opened into the pleural cavity and ultimately presented itself at the left hypochondrium. The pus which flowed out from this part in abundance, was also ejected through the bronchi. When the patient vomited the wound in the side closed up; but when, on the contrary, the pus issued at the hypochondrium the vomiting was arrested, and this condition of things did not ter-

minate until after the expiration of fifteen months. I have met with two other cases of this description, and MM. Jaymes, (*Journ. Gén. de Méd.*, t. 48,) Roc, Wioley, and Davies (*Revue Méd.*, 1836, t. II., p. 260,) have mentioned other similar ones. A peasant in the environs of Tours, operated upon in 1814 by M. Gouraud, was perfectly restored. Freteau, (*Journ. Gén. de Méd.*, t. XLVII., p. 121,) Ollenroth, (*Dict. de Méd.*, 2d edit., t. II., p. 431,) and Audouard (*De l'Empyème, &c.*, 1808,) were no less fortunate. In the cases under consideration the effusion approximates in its character to external abscesses. The organism, in most cases, has adopted the precaution of surrounding it with adhesions, which more or less accurately circumscribe its limits; from whence it happens that after an opening has been made, the remainder of the pleura has nothing to apprehend from the contact of the air. In proportion as it is evacuated its walls may collapse upon themselves, and soon completely close up the void. The same remark, moreover, is applicable to sanguineous effusions, which almost always also ultimately become contracted to more or less circumscribed dimensions, under the influence of the adhesive inflammation of the surrounding surfaces.

*C. Effusions of serosity.*—Serous effusions do not present the same chances of success. The surfaces which supply them are not sufficiently irritated, at least in general, to contract adhesions with each other. The lung gently pushed back towards its root, and soon deprived of all permeability, is then incapable of resuming its natural dimensions, and the chest being once opened into, may place the whole extent of the pleura in contact with the air; so that many surgeons, in such cases, reject even the very idea of the operation. Nevertheless if all the means that reason or experience point out have been tried in vain, if it be not positively ascertained that an incurable organic lesion is the cause of the effusion, and if the alarming symptoms and suffocation threaten the life of the patient, the operation of empyema is a last resource, which it would be unjustifiable not to perform. M. Gouraud effected a remarkable cure by it in 1808. We owe one also to M. Tuson, (*Lond. Med. Gaz.*, June, 1837, p. 396,) who, in this manner, extracted nine pints of liquid from the thorax after a pleurisy. M. Caffort (*Private Letter*, October, 1837,) informs me that he has succeeded in four cases out of six; and scientific collections in various places, contain other examples, which I shall shortly speak of. The artificial subtraction of a portion of the effused liquid, so actively promotes absorption in the pectoral cavity, that several practitioners have considered that the operation of empyema should be laid down as a rule after pleurisies whose resolution can be no longer hoped for. It must be confessed, however, that it rarely succeeds under such circumstances. The patient mentioned by M. Martin Solon, (*Journ. Hebd.*, 1830, t. II.,) who declares himself its advocate, perished. The same was the case in the patient operated upon in 1830 at La Charité, and with the one whose thorax was opened into at the hospital of St. Antoine, while I was in service there.

*D. Effusions of Gas.*—The presence of air or gas in the interior of the pleural cavities, which so many physicians have noticed since Itard made it the subject of an interesting memoir, whether it be

caused by the laceration of a pulmonary cell, the decomposition of certain liquids or by a pure and simple exhalation, is also one of those cases which might possibly require the perforation of the thorax. Riolan and H. Bass have had evidence of this in patients in whom the chest, instead of the pus they expected to find there, contained in reality nothing but air. The researches of A. Monro and Gooch, and especially of Hewson, leave not the slightest doubt upon this subject. Nevertheless it is not to be forgotten that under such circumstances it is a symptom of but trivial importance in itself, that may disappear spontaneously, and that if it is accompanied with a deep-seated organic alteration, the operation of empyema will afford but temporary relief.

### § II.—Appreciation.

The successful results obtained from the operation for empyema, moreover, are very numerous at the present day. Besides those above, Baillou, (Bonet, *Corps de Méd.*, t. IV., p. 558.) who made his incision between the fifth and sixth ribs, also mentions one; Marchettis (*Ibid.*, t. III., p. 247) mentions two; and Rey, who left a canula in the wound, two others. We are indebted also for two to M. Martini (*Bull. de Fér.*, t. VII., p. 162;) for one to M. Norfini (*Ibid.*, t. XVII., p. 648;) three to M. Herpin (*Precis d'Indre et Loire—Gaz. Méd.*, 1833, p. 417;) three to M. Reybard, (*Arch. Gén. de Méd.*, t. XVII., p. 648.) and two to MM. Tourdes and Malle, (*Bull. de l'Acad. Roy. de Méd.*, t. I., p. 402.) Out of six cases, M. Rey (*Arch. Gén. de Méd.*, 2d ser., t. XII., p. 338) counts four cures; M. Dieffenbach (*Gaz. Méd. Chir.*, t. II., p. 56) has cured three out of four; M. Roque (*Bull. de l'Acad. Roy. de Méd.*, t. I., p. 457) three out of five, and M. Davies (*Encyclogr. Méd.*, p. 49) eight out of ten cases. M. Faure, (*Bull. de l'Acad.*, t. I., p. 62,) however, has obtained only one or two cures out of eight cases, and though MM. Roux, (*Ibid.*, pp. 65, 101,) Bricheteau, (*Ibid.*, p. 124,) Brigham, (*Gaz Méd.*, 1833, p. 324,) Larrey, (*Bull. de l'Acad. Roy. de Méd.*, t. I., p. 160,) and Caffort (*Private Letter*, October, 1837) have each in their turn seen it succeed, and that M. Guérard, (*Arch. Gén. de Méd.*, t. XIII., p. 270,) performing it twice on the same subject at an interval of forty years, has been no less fortunate; though in spite of a syphilis and carious rib, another patient (*Gaz. Méd.*, 1833, p. 418) has also been restored by it, and that M. Reybard has cured almost all those whom he has operated upon,—this operation, nevertheless, has been unattended with success in an infinity of other cases. Performed by M. Bégin (*Elem. de Chir.*, 2d edit., t. II., p. 37) on four different patients, two of whom were attacked with effusions of serum, one with a sero-sanguineous collection caused by hemorrhagic inflammation, and the fourth with effusion of pus, it did not prevent all the four from terminating in a fatal issue after having undergone numerous punctures. I have performed it or seen it performed twelve times myself, in the hospitals of Paris, and every one of the patients died. The dangers that it involves moreover may be readily conceived. If the lung, after having been a long time compressed, has not lost its natural permeability, the air is inhaled into it with force, and may thus become the source of an irritation or violent inflammation imme-

diately after the abstraction of the liquid. Upon the supposition that this organ has shrunk so much as to yield but slowly to the mechanical action of the atmosphere, the species of void which is immediately left about the parts, which up to that time had been steadily supported, necessarily disturbs the pectoral circulation and the respiration. The air without being irritating or injurious in itself, nevertheless, most usually exercises a pernicious influence upon the subsequent symptoms of the disease. Being introduced into the chest it becomes heated and combines as it decomposes with the remains of the effused matter, which speedily acquires acrid and putrid properties which it did not possess before, and the action of which is not sustained by the system without danger. It is this new material, not the air, properly so called, which inflames the cavity and produces a general reaction, which is sometimes exceedingly intense and too often fatal; it is this also which, penetrating in greater or less proportion into the mass of the circulating fluids, infects them and gives rise to adynamic phenomena, to which a great number of the unfortunate persons thus treated fall a prey. The danger therefore would be in proportion to the extent of the walls of the collection, the degree of exhaustion, the irritability, force, and vital resistance of the patient, as well as in relation with the character of the matters effused, and with the conditions of the organs contained in the chest.

### § III.—*Examination of the Methods.*

Three points especially in the operation of empyema require the attention of the surgeon; 1st, the part of the chest at which it is to be performed; 2d, the most suitable instrument for performing it; and 3d, the kind of dressing which becomes necessary.

*A. Place of Election and Place of Necessity.*—When the effusion is not circumscribed by any adhesion, and when the pleural linings are entirely free, it is recommended to open into the pectoral cavity at the part which is the most depending and most favorable for the egress of the liquids, and this point is denominated the *place of election*; when on the contrary, the collection is situated only in one region of the chest, and that it is so exactly circumscribed that neither the position nor the movements of the patient can cause it to change its locality, the opening should be made in a determinate point, and this is what is termed the *place of necessity*. This latter has never varied, nor can it vary at the pleasure of practitioners. The other, on the contrary, being an affair of choice, necessarily cannot be nor has it been in fact the same with all surgeons. Some, for example, with F. Walther, have placed it in the fourth intercostal space, counting from above downward; others, with Leonidas and F. ab Aquapendente, in the fifth; and others, with Sharp, B. Bell, &c., in the sixth. Heers recommends that it should be in the seventh. There are those who, like G. de Salicet and Lanfranc, prefer the eighth; others, with A. Paré, the ninth. Solingen thinks that it is better to select the tenth, as recommended by A. Lusitanus, for the left side, and the ninth for the right; finally, Vesalius and Warner consider that it is the eleventh which offers the most advantages.

1. In our times we generally prefer, at least in France, *the third intercostal space* for the left side and the fourth for the right. Lower down we might wound the diaphragm or liver, or we might run the risk of passing the instrument into the peritoneum and strike below the collection; higher up we should miss the most depending part, and the liquid would not flow with all the facility desirable. To these arguments it is true it might be objected: 1. That in large collections the diaphragm, and the liver with it, is too powerfully crowded downwards to be wounded even when we penetrate between the second and third rib; 2. That we may change at pleasure the depending point of the thorax by giving this or that position to the patient, and that under this point of view the sixth or ninth intercostal space is nearly as advantageous as the third; but as there is moreover no inconvenience in following the precept adopted among us, it would be as advisable to conform to it as to seek for another; so much the more so as the sensation of suffocation which usually distresses those who are afflicted with effusions in the chest, renders any other position difficult for them than that which more or less approximates to the vertical one. Only that I do not consider that we should restrain ourselves too rigorously to perforate above the third rather than the fourth rib, when any difficulty should exist in distinguishing them.

II. *The intercostal space having been once decided upon*, it remains to be determined upon what point of its length the operation should be performed. If very near the sternum, the internal mammary artery might be wounded; farther to the outside is found the descending branch and anastomosing branches of this vessel. In the direction of the spine is situated the mass of the sacro-lumbar and longissimus dorsi muscles; a little farther upon the side, the trunk of the artery not being yet concealed or protected by the lower border of the rib, might be easily opened into. It is therefore with reason that a choice has been made of the point at the union of the posterior third with the two anterior thirds of the contour of the thorax. At that part the incision strikes in front of the latissimus dorsi muscle, between the bundles or digitations of the serratus magnus and obliquus externus abdominis. We have nothing to divide but the integuments, the intercostal muscles and the pleura. The artery now lodged in the infra-costal groove is not yet bifurcated, and the space is sufficiently large to admit the extremity of the finger. Nevertheless if this place should not offer moreover the very important advantage of being the most depending when the patient is slightly inclined upon his side, or seated or lying down, there would be no inconvenience in making the opening farther behind or in front, as David and several other practitioners have recommended.

III. Many *methods* have been proposed to *determine* with precision the position of the third intercostal space. If the patient is thin, all that we have to do is to count the ribs from below upwards; but when œdema or a thick layer of cellular or adipose tissue covers the ribs, we are obliged to proceed in another manner. According to some, when the hand of the patient is placed over the front part of the sternum and the arm left pendent upon the side of the trunk, the elbow when slightly pushed backwards, corresponds exactly to the

space sought for. This mode of exploration, besides being very inexact, is much better calculated to conduct us between the two last ribs than between the ninth and tenth; and that which consists in descending to six fingers' breadth below the lower angle of the scapula in order to perforate the chest, would be infinitely more certain and more rational if this locality had really the value which was formerly accorded to it.

IV. Formerly it was a matter of great importance to mark out the *place of necessity* in the operation for empyema. If there was no manifest tumor or thickening of the tissues externally, if a cataplasma which should become dry at an earlier period, according to some, or remain on the contrary a longer time moist, according to others, when placed over the effusion, indicated nothing, it would be necessary to depend upon the sensations experienced by the patient, or to succussion or other means still more fallacious. But the labors of Avenbrugger, Corvisart, Laennec, and M. Piorry, have fortunately dispelled this uncertainty; so that now it is almost as easy to recognize the precise seat and limit of collections in the interior of the chest, as if they were upon the surface of the body.

B. *Instruments*.—Whether for the purpose of guarding against hemorrhage, or for obtaining a wound with loss of substance, or because they considered *escharotics* to possess particular virtues, the ancients and many authors of the middle ages, in order to open into the chest, frequently had recourse to cauteries either chemical or *metallic*. The cotemporaries of Leonidas made use of a cautery in the form of the kernel of fruit. It was also by means of the iron heated to a white heat that the Cinesias mentioned by Galen was operated upon. The cautery of Rhazes was slender and pointed, while that of Albucasis was of a triangular form. A. Paré recommended that it should be provided with a concave plate at some distance from its point. But this method, long since abandoned, would scarcely merit notice, if it had not been still eulogized by M. Gouraud, who especially uses it for effusions of pus, and gives to the hot iron the advantage of enabling the abscess to empty itself of its own accord upon the fall of the eschar, and to the wound that of resisting the entrance of the air from the tumefaction of its borders. The *scolopomachairion* of Paul of Egina, the *phebotome* of the Arabs, and the *sagitella* of Arculanus, which were formerly made use of, have also disappeared from practice. The ordinary bistoury and trochar, at the present time, are substituted for all other kinds of instruments, when it is our intention to make an opening into the chest. Though Paré had already proposed the paracentesis trochar, in order to perforate one rib rather than the intercostal space, it was not however until after Drouin and Nuck that attention was really turned towards this point. Dionis, Heister, and Morand especially advocated the employment of the trochar, which has still a considerable number of partisans at the present day, and which possesses the advantage of rendering the operation easy, prompt, and attended with but little pain, and the entrance of air into the cavity almost impossible; of not making it necessary to evacuate the entire collection at first; and of permitting in fine the repetition of a considerable number of punctures successively in cases in which this should be judged necessary.

But as on the other hand its canula possesses the inconvenience of not always allowing a sufficiently free exit to matters that are somewhat inspissated, or grumulated pus, or blood partially coagulated, for example, it is far from being applicable in all cases indiscriminately. Moreover the preference is not generally given to it except in hydrothorax and extensive pleuritic effusions. There would be no difficulty moreover in transforming a simple puncture immediately into a large wound, if the liquid at first did not run with sufficient freedom; nor can I perceive how the lung or diaphragm would incur more risk of being wounded by such an instrument than by any other. Paracentesis thoracis moreover is governed in other respects by the same rules as paracentesis abdominis, which will be treated of farther on.

*C. Auxiliary Resources.*—If our object in the operation is to relieve an effusion of air, the wound generally requires no dressing. In other cases, the course to be pursued is not so precisely established. In truth, the pyulcon of Galen, the cupping glasses, syringes, and suction, so much boasted of in the sixteenth and seventeenth centuries, in order to remove the very last drop of extravasated liquid; the different kinds of canulas employed during a long period of time, in order to prevent the pleura from closing up too rapidly, and to enable us to evacuate the chest only by degrees, have lost almost all their importance, although practitioners still ask the question whether we ought or ought not to evacuate at once the morbid collection, or to maintain a foreign body there under the character of a filter, or throw up medicated injections into the cavity rather than to unite the external opening by first intention.

Unless the lung should possess all its natural expansibility, which is a very rare circumstance in hydrothorax, there would be an undoubted advantage in not allowing the serosity to escape except by degrees, and in introducing the extremity of a band of linen or meche of lint into the plural cavity, in order that at each dressing we may procure an additional discharge. Perhaps also repeated punctures with the cataract needle or a very narrow bistoury, would deserve to be made trial of under such circumstances; nor can I see why the employment of this meche ought to be neglected in cases of empyema, properly so called, or in effusion of blood, so long as we attach importance to the circumstance of air not penetrating into the cavity. To perform the paracentesis, moreover, no other instrument is required than the trochar. The employment of injections requires all the attention of the surgeon. It was the abuse which the ancients made of these, which has induced the moderns to proscribe them almost universally. They are not applicable either in hydrothorax or in those effusions which are not limited by any adhesion. In the other cases, on the contrary, it would be difficult to contest their advantages. As soon as the suppuration has a tendency to become degenerated, they alone appear to be capable of preventing adynamia and the decomposition of the fluids, by modifying and cleansing the surface of the morbid cavity, and by favoring the discharge externally of the altered matters in proportion as they are formed. M. Billerey, and M. Récamier (*Bull. de l'Acad. Roy. de Méd.*, t. I., p. 182.) after him, who substitute and retain in the cavity emollient, detergent or

antiseptic liquids, in place of the pus which they have extracted, have had every reason to be satisfied with this practice. It is seen therefore that the precaution of strongly stretching up the skin while we are perforating an intercostal space, in order to prevent the parallelism which, unless we should do this, would be left between the opening into the pleura and that of the integuments, can scarcely be necessary, and that it is far from meriting the importance which has generally been accorded to it since Bass laid it down as a precept.

#### § IV.—*Operative Process.*

A convex or straight bistoury, or a trochar, a vessel to receive the liquid, a strip of trimmed linen, a yard long and one finger's breadth in width, some gateaux of lint and compresses, and a body bandage, form, together with a canula of gum-elastic, and a syringe, all the articles that we can require.

*A. Ordinary Process.*—The patient being seated on a bed, rather than on an arm or common chair, and more or less inclined to his sound side, is to be supported in this position by assistants in such manner that the intercostal space which is to be opened may be widened as much as possible and altogether free. The surgeon being placed upon the right and in front, stretches the skin with his left hand, and with a bistoury in his right hand divides it in a direction parallel to the superior border of the rib below, from left to right on the right side, and from himself if it is on the left side; divides successively, and in the same direction, layer by layer, the adipose covering, a thin layer of cellular tissue, the external muscles of the thorax, if there are any at the point which he has selected, and the external and internal intercostal muscle; reaches the pleura, and in order to perforate it without danger of wounding other organs, then makes use only of the point of the bistoury, resting at its back on the pulp of the left forefinger, which serves him as a director; gives to the internal opening an extent of from six lines to an inch, and penetrates in this manner into the interior of the cavity, from whence he will perceive that the liquid instantly escapes. If, as frequently happens, layers of a new formation should have become adherent to the internal surface of the pleura, the operator will have so much the less reason to be deterred by this difficulty, inasmuch as we may, if necessary, plunge into the tissue of the lung itself, when the abscess has its seat in that part. The important point is not to strike outside of the morbid collection. In event, however, of making a mistake of this kind, it would be better, unless the matter was at so small a distance that we could appreciate its fluctuation with the finger, to make another opening in a suitable place, than to persist in detaching the neighboring adhesions, either by means of the finger, handle of the scalpel or sound, or what is more objectionable, by means of a bladder introduced empty into the wound, and then filled with air or liquid while it is in the thorax, as some of the ancients recommend.

*B. Process of the author.*—The reasons adduced for laying down so many precautions in perforating the parietes of the thorax, appear to me to be but little worthy of the approbation they have received. What danger can there be in penetrating at once into the pleura, or

even in going into the lung? But this accident is not possible, except the instrument should not be directed upon the collection. Moreover, the lung is free and sound behind the wound, and then the pleura is no sooner perforated than the pressure of the atmosphere pushes the lung towards the spine; or intimate adhesions unite it to the walls of the chest, and in this case what danger could arise from a slight puncture of its parenchyma? I am of opinion, therefore, that the operation for empyema would be infinitely more simple, and in every respect as safe, if in order to perform it we should suddenly, and without hesitation, perforate the intercostal space by means of a puncture with the bistoury, held in the second or third position, that is to say, in the same manner as in external abscesses, which are opened from within outwards. We would in this way combine in some measure the advantages of paracentesis with those of incision, and the opening into the chest, which appears so formidable at first sight, would in reality scarcely deserve the name of an operation. I have performed the operation five times by this process, and have not been able to comprehend what advantage there would have been in making use of others. M. Caffort also writes me that he has several times had recourse to it with success.

V. *Dressing*.—I designedly omit speaking of the precept of those who recommend that before incising the integuments, we should take up a large fold of them perpendicular to the ribs, in place of stretching them with the hand, and that of some others who have supposed that the incision of the skin ought to be vertical and not horizontal. It suffices to mention such opinions, to enable every person to appreciate them at their just value. I shall take still less notice of the method of Mercati, which consists in penetrating only as far as the pleura, and without wounding that membrane, in order that the liquid may of itself effect the perforation. It would be equally absurd to finish the operation with a lancet, after making use of the bistoury for its commencement. The object is to arrive with certainty and without danger into the morbid cavity. Nothing, certainly, can be less difficult, and it is not assuredly in this point of view that the operation of empyema should be deemed formidable.

A. An effusion to such extent as to require surgical aid, might cause the death of the patient, if it should be formed at the same time in both sides of the thorax, before we could venture to attempt the operation. Upon the contrary supposition, it would be necessary to follow the rule formerly laid down by A. Benedetti: that is, not to open into the two pleural cavities, until after an interval of some days, and to adopt all the precautions necessary to prevent the crowding back and contraction of the two lungs.

B. If the operator does not wish the wound to remain open, he approximates its lips as soon as there is no longer any liquid to extract from the thoracic cavity, keeps them in contact by means of a strip of adhesive plaster, then covers them with a gâteau of lint, followed by a compress, and secures the whole by means of a body-bandage drawn moderately tight. If the whole of the matter has not been evacuated, the flat dressing with lint besmeared with cerate, is generally sufficient to prevent the too speedy adhesion of the borders of the perforation. In order, however, to have our

minds at rest on this point, there is no objection to the surgeon inserting into the solution of continuity, by means of the meche-holder, a small cone of lint or one of the extremities of a linen band prepared for this purpose : in other respects he is to proceed as above. The tents which were formerly employed for this purpose, and which were attached outside by means of a thread, besides the inconvenience of forming a plug, also possessed, as in the example related by Guy, that of the possibility of their escaping into the morbid cavity and becoming lost there.

C. So long as the fluids that flow out at each dressing, preserve their primitive character and do not deteriorate, injections could not but be injurious. We ought to have recourse to them, on the contrary, upon the slightest change being manifested. Under this point of view, tepid water at first, sweetened barley water, diluted lime or lead water, or a weak decoction of bark, are to be successively or alternately used, also other detergent, astringent, or antiseptic liquids, which the practitioner will know how to select according to the indication. M. Bache, (*Thèse*, No. 66, Paris, 1827,) avers that this method which has been for a long time adopted at the Hospital of Grenoble by M. Billerey, who, moreover is in the habit of closing the wound in the interval of the dressings, by means of a plug of gentian, has been frequently attended with complete success in that establishment.

D. The apparatus contrived by M. G. Pelletan, (*Bull. de l'Acad.*, t. I., p. 227, or *Gaz. Méd.*, 1830, p. 185,) and which by means of canulas and valves, (soupapes,) permits the establishment of a double current for the liquid, while preventing at the same time the introduction of air into the thorax, which apparatus moreover is based upon the same principle as that of M. Héroldt, is too complicated and of too little importance for practitioners to assent to its employment. I would make the same remark of those which have been since proposed by MM. Bonvier, (*Bull. de l'Acad. Roy. de Méd.*, t. I., p. 73,) Maissiat, Récamier, (*Ibid.*, p. 182,) &c. The small canula provided with a perforated sac of goldbeater's skin, made use of by M. Reybard, (*Mém. sur les Anus Artific.* &c., p. 157,) would be at once more certain, simple, and convenient, if it were advisable to adopt any precaution to prevent the entrance of air into the thorax.

[*Paracentesis of the Thorax.*—M. Trousseau, (*Arch. Gén. de Paris*, 4e ser., t. VI., Sept. 1844, or *Journal de Médecine de Paris*, Novembre, 1843, and Aout, 1844,) advocates this operation, where there is decided effusion and displacement of the heart, not only in chronic but also in acute cases of pleurisy. He has performed it once in acute, and twice in chronic pleurisy, and in both the latter, as he thinks, it saved the life of the patients. Laennec had also long since recommended it as a dernier resort in such cases, to prevent immediate suffocation. Our remarks on tracheotomy, (see notes supra,) apply to paracentesis thoracis. As to the danger of the lungs being suffocated, as Laennec considered, by the compression of the diffused fluid in the pleural cavities, this is doubtless possible, where active depletion has been neglected. But certain it is, that one lung may be gradually almost entirely absorbed by compression from such fluid, without causing death. While at the Seamen's Retreat, I saw a striking case of this in a patient who died of a protract-

ed hydrothorax and general dropsy. One lung was reduced down to the size of a dog's ear, and was floating in an ocean of circumambient transparent serum in the pleural cavity, and this without the normal organic structure of the lobes of this miniature lung being apparently in the least degree altered! T.]

## ARTICLE II.—WOUNDING OF THE INTERCOSTAL ARTERY.

### § I.

Upon the supposition that the *diaphragm had been wounded*, during the operation of empyema, an instance of which was witnessed by Solingen, we should have no other resources than those of medicine to oppose to it, and the wounding of the intercostal artery is, in fact, the only accident which in these cases can require the interposition of surgery. Though rare, this wound, however, has occupied much of the attention of authors, to so great a degree in fact, that the number of remedies that have been proposed for its relief, perhaps exceed that of the number of times that the accident has occurred, unless perhaps it be that it has been frequently overlooked and the proper remedy neglected, even in those cases in which the effusion, which it has produced, has resulted in a fatal issue, an example of which has been published by M. Thierry (*Bibliot. Méd.*, 1828, t. I., p. 240.) The cases in which it has been especially met with, are those from wounds penetrating into the chest. It is recognized by the hemorrhage which it occasions, the symptoms of effusion which follow, the paleness, syncope, &c. A piece of card introduced into the bottom of the wound and curved into the shape of a gutter, enables us to ascertain the direction from whence the blood escapes. The finger glided under the rib will frequently distinguish a hot or pulsating jet of blood difficult to be mistaken, and forms one of the surest diagnostic marks when its employment is practicable.

### § II.

*Gérard*, by means of a thread introduced into the wound, and brought from within outwards by the aid of a curved needle, through the intercostal space above, conducted a tent below the artery, which he hoped in this manner to compress by constricting the entire circumference of the rib. *Goulard*, with the view of rendering it unnecessary to withdraw the whole of the conducting instrument through the new wound, contrived a needle with a curved handle, like that of *Gérard*, pierced with an eye near its point, and hollowed out upon its convexity with a groove which was intended to receive the thread. *Heuermann* alleges that by means of a needle strongly curved and fixed at an angle upon its handle, we may surround the bone in such manner as to bring out the two extremities of the thread through the same wound. *Leber*, after having made a second opening above the rib, used this opening to conduct a thread which he caused to come out through the wound, and the two ends of which he afterwards knotted upon a compress after the manner of *Gérard*. To effect this, he made use of a flat and flexible sound, which *Steidèle*

has replaced by one of silver, curved into the shape of an S, and for which *Boestcher* has, according to *Sprengel*, substituted a smooth and blunt-pointed steel sound. Finally, *Reich*, instead of fastening the thread by a knot, recommends that its extremities should be passed through a gum-elastic canula, which is to be secured outside ; but all these processes are useless, as well as the double plate of *Lottery*, the *jeton* of *Quesnay*, and the *machine* of *Bellocq*.

### § III.

Nor does the *tent strangulated* in its middle portion by a thread tied strongly around it, and then introduced transversely into the pleura, and afterwards placed in a vertical position, in order that when making traction upon it, it will no longer be possible to draw it out, and that it may compress at the same time the artery as well as the borders of the two neighboring ribs, deserve the eulogies that have been bestowed upon it by *Bilguer*, *Richter*, *Desault*, and *Sabatier*. *Theden* maintains that in order to arrest the hemorrhage, nothing more is required than to complete the division of the artery, reverse its posterior end backwards, and tampon the wound. I will remark that we may frequently effect the same result without reversing the vessel, as has been shown by *Hebeinstreit*. It is difficult to understand why *Loeßler* should have thought it proper to recommend an opening into the intercostal space a little farther behind, leaving the pleura intact, in order to divide the artery at this point, and to apply the tamponing there, without interfering in any respect with the exit of the effused matters, through the first opening.

### § IV.

*Bell*, rejecting all these processes, finds it more convenient to seize with a hook the end of the wounded vessel, and to apply a ligature to it immediately. There are those who have ventured to establish a point of compression upon the wound of the vessel during the space of several days, by means of the fingers of assistants alternately relieved. But upon the supposition that prompt action was necessary, we might readily arrest the hemorrhage by introducing after the manner of *Desault* and *Zang*, the middle portion of a fine compress into the chest. After having filled the bottom of this kind of sac with lint or tow, to transform its internal portion into a pelote, there would be nothing more to do than to shut up its external portion and make traction upon it, in such manner as to compress from within outwards, until the blood had ceased to flow. This small apparatus moreover could be readily secured, by tying the free portion of the linen for example, upon another pelote of lint. This resource, the only one to which *M. Larrey* gave his assent, when from any reason whatever it was not judged practicable to attempt immediate reunion of the wound, being applicable to all cases, and possessing the advantage of being always at command, and of being readily understood by every person, ought to have the preference over all the others, and should unquestionably be substituted for them.

## ARTICLE III.—PARACENTESIS OF THE PERICARDIUM.

§ I.—*Appreciation.*

The idea of opening into the pericardium when filled with serosity, pus or blood, appeared so bold at first that many persons still look upon it as rash and unwarrantable. Timid surgeons have been deterred by it from the fear of wounding the heart. Others reject it because it might excite an inflammation which, from its situation, would speedily result in death. The difficulty of recognizing the disease with certainty during life, and the objection that we should give relief only to one symptom, is the argument which the most judicious have adduced against it. None of these various objections, however, are of a character to cause it to be absolutely proscribed. The skilful practitioner, aided by the explorative resources that science possesses at the present day, will rarely find himself incapable of establishing a diagnosis of effusion in the pericardium. The heart may be always avoided. By evacuating a serous membrane of the liquid which has accumulated within it, we disembarass it of a foreign body, and the puncture is in this sense more calculated to diminish than to give rise to inflammation. It is true that with the operation the patient is exposed to great danger; but without it he is devoted to a speedy and certain death. If the paracentesis does not cure, it may at least afford momentary relief. Nevertheless it is unfortunate that experience should have furnished scarcely any elucidation; and that it should still present only ideas that are purely theoretical upon a subject of so serious a nature. Senac, who has been erroneously thought to have been the first to propose puncture of the pericardium, gives no instance of it, and the case imputed to him by Sprengel relates, in reality, to hydrothorax. Van Swieten and H. Welse, referred to by M. Rayer, express themselves still more confusedly. Nor does Riolan, who speaks of it as a general suggestion, assert that it had been performed in his time. It is well known that the pretended pericardium that Desault supposed he had opened, was nothing else than an accidental cyst. We do not find that M. Skielderup has furnished anything conclusive in support of his opinions. It is also evident that the collection which was opened by M. Larrey was situated external to the pericardium. The three observations related by M. Romero, (*Bull. de la Fac. de Med.*, t. IV., p. 273,) and the substance of which has been given by M. Mérat, are too imperfect not to leave the mind in considerable doubt. The one that M. Jowet (*Bull. de Fêrr.*, t. XIII., p. 233,) has published in 1827, as the first instance of a successful result, is also incapable of removing all doubts upon this subject. But though it may still remain to be demonstrated that paracentesis of the pericardium has ever been performed upon living man, except perhaps in the case which M. Warren has communicated to me; facts are not wanting to show indisputably that the perforation of this membrane does not necessarily cause death. The thesis of M. A. Sanson furnishes many proofs of this. M. Larrey also relates several, and I myself have collected other examples.—(See *Wounds of the Heart*, Vol. II.)

§ II.—*Operative Process.*

The pericardium, in its natural state, is accessible at a great number of points to surgical means. Effusions, by distending it to an abnormal degree, would enable it to be still more readily attacked.

A. Riolan maintains, and others have agreed with him, that we may puncture the pericardium by *trephining* the sternum, an inch above the xiphoid cartilage. This opinion, revived as a new one, and with all the necessary details, by *M. Skielderup*, has found some partisans among the moderns. Laennec, among others, adopts it, and endeavors to demonstrate its advantages, which are that of avoiding with certainty the internal mammary artery, that of going down inevitably upon the distended pouch, and of not making an opening into the pleura. *Senac* recommends that we should make the opening in the fifth or sixth intercostal space, a little to the left of the sternum, and that the *trochar*, introduced at that point, should be introduced very obliquely downwards, and to the right, until it reached the collection to be evacuated. *Desault*, in order not to wound the mammary artery, made his incision more to the outside, and did not penetrate into the morbid collection until after having identified its fluctuation by means of the finger. This also is the method which is eulogized by *M. Romero*, who, in place of the trochar of *Senac*, or the blunt-pointed bistoury of *Desault*, preferred the scissors for dividing the pericardium, after having raised up a fold of it by means of the forceps. Finally, *M. Larrey* considers it better to perforate from below upwards, the space which separates the left border of the xiphoid appendix, from the cartilage of the last true rib; that we would in this manner avoid the pleura, incur no risk of wounding the peritoneum, diaphragm, or internal mammary artery, and would strike upon the most depending part of the pericardium.

B. Trephining of the sternum unquestionably is the most simple process which has been proposed. The bone which is thus perforated is soft, and superficial, and destitute of vessels on both its surfaces. It enables us to see and to touch the pericardium before opening it, and to forego the last stage of the operation, which is the only one that is dangerous, should the surgeon have misconceived the situation of the hydropsy. The fluid cannot be effused into the pleural cavity. I see no other inconvenience in it than that of occasioning a loss of substance, which renders the immediate reunion of the wound difficult, and which unavoidably places the interior of the cavity in contact with the atmospheric air. But is it not better to leave the perforation of the pericardium open, than to shut it up before having removed the source of the mischief? Is not the action of the air, in such cases, a result which is rather to be desired than to be dreaded? The danger which the pleura incurs, whatever precaution we may take to avoid it, and also the internal mammary, in the method of *Senac*, slightly modified by *Desault* and *MM. Romero* and *Jowet*, are certainly not considerations that ought to outweigh the preceding process. The process of *M. Larrey*, which might possibly procure the same result as the trephining of the sternum, is not so easy of application as its inventor supposed in

subjects in whom œdema, infiltration, or embonpoint exists, to such extent that the skin does not come into immediate contact with the external surface of the bones or cartilages of the thorax. The branch of the mammary artery, moreover, which crosses the anterior face of the ensiform prolongation, is sometimes so voluminous that its division, which is almost unavoidable, might give rise to an alarming hemorrhage. In conclusion, therefore, it would appear to me prudent to adopt the advice of Riolan, which is also sanctioned by Boyer. The crown of the trephine should be applied upon the left half of the sternum, immediately above the xiphoid appendix, in order that it might fall upon the broadest portion of the anterior space of the mediastinum. The left forefinger introduced into the bottom of the wound would then enable us to identify the fluctuation, and would serve as a guide for the bistoury. Having opened into the pericardium, it would become advisable to turn the patient upon his left side, and more than ever to keep his chest in a position almost vertical, in order to give egress to the liquid, which should be allowed to flow out gently. The dressing would consist of a meche introduced into the orifice of the serous sac, a plumasseau besmeared with cerate, some compresses, and a body bandage, in order to support the whole, precisely as in the operation for empyema.

C. *Injectiōns.*—The idea of treating hydropericardia in the manner of a hydrocele, and of injecting an irritating liquid into the diseased cavity in order to promote adhesive inflammation, has nothing in it repugnant to sound reason, and those who have reproached M. Richerand for having suggested it, have done so improperly. If the puncture, besides evacuating the liquid, does not in itself cause adhesion, it is useless to count upon its affording relief, except as a simple palliative. The radical cure of hydropericardia without obliteration of the altered sac is no more possible than that of hydrocele. If it ever has been obtained, it is because the practitioner, without having intended it, has carried out the indication first proposed by M. Richerand, and since by Laennec. The contact of the air, moreover, would perhaps suffice to bring about the necessary degree of inflammation. When there is no organic lesion, tepid water or some other liquid only slightly irritating, should be first made trial of. Should the case be one of effusion of pus, the injection should be varied according to the indications, in the same way as after empyema. In whatever manner performed, I should recommend that the incision into the pericardium, when the bistoury is made use of, should be large, and that it should be kept open until the termination of the treatment. The treatment would be then analogous to that of hydrocele by incision or excision, and the effusion which generally follows the injection of the tunica vaginalis after puncture would not jeopardize the final result. If the case should be one of serous effusion, I should prefer after having laid bare the part, to plunge in a trochar and after having emptied it to inject it, with a solution of tincture of iodine, as is my general practice in hydrocele. It is probable that we might in this manner effect an agglutination of the pericardium to the heart. These however are nothing more than suppositions. Before attaching any value to them or applying them

to living man, we ought, by experiments upon living animals, to ascertain how far they are founded on truth. It is a point in practice which cannot cease to be interesting. The rarity of the cases which would enable us to take advantage of it is the only plausible reason which appears to me to diminish its importance.

## PART FOURTH.

### ABDOMEN.

#### CHAPTER I.

##### EFFUSIONS, CYSTS AND FISTULAS.

###### ARTICLE I.—PARACENTESIS.

Puncture of the lower belly in cases of *dropsy* is one of the most ancient operations of surgery. The first suggestion of it must have been derived from accidents, of which history furnishes a great number of examples. Nothing in fact is more common in the annals of science, than cases of ascites cured in consequence of a wound of the abdomen. A child, says Meysonnier, (*Cours de Méd.*, 7th edit., 4to, p. 276,) who was amusing himself in playing with a knife in the yard of a peasant who had ascites, was thrust by his little companions against the unfortunate patient, and cut an opening into his belly. A great quantity of water ran out through the wound, so that at the expiration of a few weeks the patient found himself radically cured! Another ascitic, finding no surgeon willing to undertake the puncture, resolved to perform it himself. Prohibition having been made to allow any thing to be placed at his disposal which could enable him to carry out his intention, he concluded to break the glass which he used for drinking and shape out a piece of it, which he plunged in below the navel. A radical cure was the reward of his temerity. There is no doubt that the same circumstances have led to the same result in the remotest antiquity, and that paracentesis abdominis is as ancient as medicine itself. A patient operated upon by M. Isabeau, though affected at the same time with hydrothorax, was perfectly cured of his ascites. M. Dupasquier, who in another case had recourse to diuretics after puncture, was no less fortunate.

###### § I.—*Indications.*

When the ascites is the result of an incurable affection of one of the organs contained in the belly, it is evident that puncture cannot cure it, and that we must then resort to this only for the purpose of procuring temporary relief to the patient. But if the dropsy is *essential* and idiopathic, the extraction of the effused liquid cannot but favor the action of the general treatment and co-operate in the re-

establishment of the health. In the first case we should not operate but at as late a period as possible, and to prevent suffocation; in the second case, it would be advisable to adopt the recommendation of Duverney and Bertrand, as revived by Broussais, and give egress in good season to the effused liquid.

A. *Compression*.—It is so seldom that we see ascites terminate fortunately, that after having unavailingly made trial of the means that experience appears to have placed most confidence in, for example, *compression*, which I have seen succeed in one instance in a boy fourteen years of age at the hospital of Tours, in 1818, and the advantages of which are eulogized by M. Speranza (*Bibl. Méd.*, 1829, t. II., p. 242,) and M. Godèle, (*Revue Méd.*, 1831, t. I., p. 12,) and the good effects of which were recognized at the Hotel Dieu in 1831, and its efficacy since placed beyond all dispute by M. Brichteau, (*Arch. Gén. de Méd.*, t. XXXIII., pp. 75—93,) it is allowable to appeal from these modes to the operation, however feeble may be the hope of its success. It must be that MM. J. Darwell and J. Copeland, (*Cyclop. of Pract. Med.*, vol. I., p. 169,) who were desirous of having it proscribed in practice, and who have advanced against it a great number of unmerited reproaches, have not seen it employed in practice, or have been rarely witnesses to the distress which ascites sometimes occasions.

B. Temporary *blisterings*, recommended by Trouvé, (*Arch. Gén. de Méd.*, t. XVIII., p. 200,) have been employed by myself of a size which might be called *monstrous*, and in my opinion deserve farther trials.

C. Encouraged by what Thouvenot says of his needles and small canulas, by what I have seen myself, and by what has been stated in England, of acupuncture in hydrocele, I was desirous also of making trial of this method, after the manner of M. King, in ascites. Having plunged in upon five or six points of the belly a long common or cataract needle, and having repeated this process three or four times in the space of fifteen days upon two women, I saw an improvement take place which surprised me, and which would justify additional trials of the same description.

## § II.—*Examination of the Processes.*

A. *The red hot iron* formerly used, caustics by which an ulcer was first made, and which it was afterwards necessary to lay open in order to reach the peritoneum, together with the *seton*, as recommended by others, have long since given place to more rational processes. The method of Paul of Egina and Guy de Chauliac, which was still lauded by Pigray, and which consists in dividing the integuments by means of a *bistoury*, and then perforating the aponeurosis or muscles a little higher up, in order to be enabled to shut up at pleasure the deeper wound, by allowing the skin, which had been previously raised up, to glide over in front of it, has been also abandoned, as well as all those which were performed by means of a cutting instrument.

B. *The needle*, and the small canulas of Thouvenot, (*Planque, Bibl.*, t. V., p. 665,) or of Barbette, evidently indicated by Rhazes, the

instrument of Block or Girault, and the trochar canula of Sanctorius, the invention of which Camper pretends to trace up to Hippocrates, variously modified by others, especially by J. L. Petit, who constructed from it the instrument known at the present day under the name of trochar or trois-quarts, render the puncture of the abdomen so simple and easy, that for a century past there is no longer any more question of the bistoury or lancet than of the cautery, when our intention is to penetrate into the peritoneum for ascites.

C. Some modern surgeons, however, seem desirous of reviving the method by incision. Physick, among others, alleges that the operation is much less painful with the lancet than with the trochar, and Dorsey says that in America this last mentioned instrument will soon fall into disrepute. M. Callaway, a surgeon of London, has more recently endeavored to prove that we ought in reality to give preference to the lancet in puncturing the lower belly. Guided by the left forefinger, which serves as a point d'appui to it, we introduce it with the right hand on the linea alba above the pubis; we then immediately insert, through the wound into the cavity of the peritoneum, a female catheter, when the operation has no longer anything particular. This process, which had already been proposed by Petit-Radel, and which is the same in fact as that of Cælius Aurelianus, might be followed without inconvenience; but it is doubtful if in fact it possesses any real advantages over the method adopted among us. If the cutting instrument encounters any vascular branches, it divides them unavoidably, and all the organs within its reach will be exposed to the same casualty; while the trochar separates apart, and rather displaces than divides the movable organs which present themselves in front of it. The wound made by its passage immediately closes as soon as the instrument is withdrawn. That which the lancet makes, on the contrary, remains open, and presents no obstacle to the egress of the serum through it.

D. The *flat trochar* of Wilson, or the flattened one (*méplat*) of Andre, which, by the advice of B. Bell, many practitioners in Great Britain prefer to Petit's instrument, because as they assert it scarcely differs from a cutting instrument, is wholly undeserving of such a predilection. The jointed trochar, those in which the point is conical, serpent-tongued, or more or less flattened, in place of being triangular, together with the fifty other descriptions which have been extolled, are not worthy of being mentioned. The one which has received the approbation of the French surgeons leaves nothing to desire, and the modifications which have been attempted upon it since the time of J. L. Petit are calculated only to render it less perfect.

I. *Place of election*.—All parts of the belly are not equally suitable for paracentesis. The *left flank* would be more favorable when the spleen is sound, if the epiploon, which extends further upon this side, did not present any obstacle to the egress of the liquid. Upon the *right side* we should have to fear the presence of the liver; while were we too near to *Poupart's ligament*, we might encounter the sigmoid flexure of the colon or the cæcum. *Posteriorly*, we have the last false rib or crest of the os innominatum, and we might readily wound the lumbar portion of the colon. The *supra-umbilical zone* corresponds to the transverse portion of the large intestine.

*Far down* upon the median line we encounter the bladder. We must select, nevertheless a depending part. The *linea alba*, preferred by the ancients, and even still by most English surgeons, has no advantage in this respect; and it is far from protecting us with as much certainty as has been supposed, from every kind of hemorrhage. A large vein sometimes runs over its posterior surface, and M. S. Cooper mentions a case in which more than a pint of blood came from a wound which he made in this place with a bistoury.

a. In *women* there is found between the womb and the rectum at the bottom of the pelvis, a *cul de sac*, by which we could readily reach through the postero-superior part of the *vagina*. This, which is the most depending point of all, would also be perhaps the most suitable, if the peritoneum were free throughout its whole extent, and if any change whatever in the relations of the bladder, uterus, or intestines, would not unavoidably expose to the risk of perforating one of these organs. We ought not therefore to select it, nor to conform to the rule laid down by Henckel, Watson, Bishop, and Noethig, until after having satisfied ourselves by the touch, that the serum had descended down as far as the pelvic cavity, and that it has a tendency to depress the upper part of the *vagina*.

b. In penetrating by the *rectum* above the *vesiculæ seminales*, as some other practitioners recommend, there would be still greater danger of wounding the bladder. The danger of finding stercoral matter afterwards passing through the rectum into the peritoneal cavity, will be sufficient to cause this route always to be rejected, though it might be adopted in certain cases as an exception.

c. Even the *bladder* has been perforated for the purpose of emptying the peritoneal cavity of dropsical patients. M. H. Bérard mentions a case in his thesis. A case was thought to be *ischuria*. The sound was forcibly introduced into the urethra, when several pints of serum escaped, and the patient died. The opening of his body proved that it was *ascites*, and that the instrument had entered into his belly. A surgeon of London, M. Watson, has gravely proposed to penetrate designedly by this route, and what is not less surprising, one of his countrymen, M. Buchanan, states that he has done it in three instances with success; but it will never be necessary among us, I think, to seriously undertake the refutation of a principle like this.

d. The *scrotum*, which is the best route, as the observations of Le Dran and Morand show, when there is at the same time *ascites* and congenital hydrocele, can be applicable only under these circumstances. If we should meet with a region in the abdominal parietes more attenuated than others, to such degree as to be formed only by the skin, and to have acquired a sort of transparency, this is the place we should select, however unfavorable it may be in other respects.

e. *The navel*, which frequently presents this peculiarity, and which Lanfranc and the two Fabricii recommend, is the point which M. Ollivier, (*Arch. Gén. de Méd.*, t. VI., p. 178,) on the strength of a fact occurring in his own practice, and on another in that of M. Bigot of Angers, proposes to perforate in *pregnant women*. Scarpa, (*Bull. de Fér.*, t. II., p. 256,) on the contrary, and after him M. Langstaff, (*Arch. Gén. de Méd.*, t. VIII., p. 267,) or M. Cruch,

recommend that during pregnancy the puncture should be made in the left hypochondrium, that is, a little below the third false rib. Like M. Emery, who says he has performed it six times in a single female, I have had recourse several times to paracentesis in women in the state of gestation, and three times, among others, during the same pregnancy. The whole extent of the left flank and all the points on this side where the trochar is usually applied, have seemed to me, separated from the womb by an interval of too great an extent to make it necessary to attach much importance to the precepts of Scarpa.

f. A little to the *outside of the linea alba* where the puncture was formerly made according to the recommendation of Celsus, we incur some risk of wounding the epigastric artery. The middle of the space that separates the ribs from the spine of the ilium, as indicated by Sabatier, would have the inconvenience of being too near the chest, should the spleen and the liver be affected with any engorgement; so that, as a general rule, the middle of the line which extends from the umbilicus to the antero-superior spinous process of the ilium is still the one which should have the preference. Here the instrument can touch neither the bladder nor the womb, unless either should be very much developed, nor the epigastric artery which is on the inside, nor the anterior iliac artery which is to the outside, nor the colon which is behind and below. This place, which the majority of operators have recommended should be chosen since Palfin first suggested it, is therefore the true *place of election*, and any of the others the *place of necessity*.

g. In ordinary ascites the wounding of the intestines or their arteries is next to impossible. The contained serum must naturally push them towards the diaphragm or in the direction of the spine. Though they should even remain free and floating, the mesentery is not long enough for the trochar to reach them. But should a noose of intestines have become adherent to the walls of the abdomen, there is no doubt that the instrument might open into them and give egress to fecal matters, examples of which are on record.

II. *Encysted dropsy*, which may have its seat in an ovary, in the cavity of the epiploons, in a portion of the peritoneum limited by adhesions, or in some particular accidental sac, would also incur the risk of the same accident. Being surrounded by thick walls we are compelled in most instances to penetrate deeper, sometimes, according to Mouton, to the distance of four inches before reaching the collection, which consequently makes it necessary that it should be identified if possible before commencing the operation.

III. *Position of the patient*.—No one at the present day recommends that the patient should stand up during the operation, nor except under certain circumstances is it convenient for him to be seated in a chair. The proper position for him is upon his side and very near the edge of the bed. While the liquid is running out, an assistant, stationed upon the opposite site, gently compresses the walls of the belly by means of his two hands broadly spread out. Without this precaution, which the ancients neglected, the viscera and the large vascular trunks, suddenly deprived of the pressure to which they had been habituated, might give rise occasionally to syncopes, swoonings and convulsions, all of which it is important to avoid. The species of

bandage or corset contrived by Monro, as a substitute for the hands of an assistant, and to be used after the operation as the dressing, though very ingenious, does not, inasmuch as it but imperfectly fulfills the indication, merit the preference which some persons have accorded to it. To apply it beforehand and tighten it by degrees as the belly is emptied, to maintain opposite to the proper place, the hole which it has on its side for the passage of the trochar, and afterwards to pad the cavities which might be left in the direction of the iliac fossæ, &c., are details too trivial to engage the attention of surgeons, unless they should be necessary. The folded sheet passed around the belly, and the two extremities of which are gradually drawn upon by two assistants while the water is running out, as recommended by M. S. Cooper, would be still more objectionable. If the effusion has its seat in the peritoneal cavity, it is possible that the epiploon, or a noose of intestine, or a flocculus of albumen or an hydatid, may become entangled in the extremity of the canula and shut it up before the liquid is completely withdrawn. A stilette or any blunt-pointed rod whatever, passed through the instrument, will be found sufficient to push aside these substances, and to give the passage of the liquid all the freedom it had at first. As serous cysts do not scarcely ever contain anything but limpid serosity, they are generally exempt from this inconvenience; but dropsy of the ovarium, which almost always consists of an oily or gelatinous matter, more or less inspissated, of a yellow, reddish or darkish color, and rarely of great fluidity, sometimes presents this difficulty, and requires at least the employment of a canula of somewhat large dimensions.

IV. *Extraction of the liquid.*—Many authors have considered that we ought not to remove all the contained fluid at once, but that it would be better to extract it by degrees. It was for this purpose that Paul of Egina, Guy de Chauliac, &c., avoided perforating the skin and peritoneum at the same point; that already at the time of Hippocrates they were in the habit of placing in the wound a small canula which has since been modified in a thousand different ways, and which was made use of in some respects as a faucet for plugging up or unplugging the opening at pleasure; that others extracted first only a small quantity of the liquid fluid to return afterwards to the repetition of the same operation a greater or less number of times; and that it was proposed, after having opened into the belly with a lancet, to leave the matter to ooze out gently and imperceptibly of itself. But as experience has furnished no positive evidence of the utility of this method, it appears to be more rational not to leave in the belly anything but that which cannot be extracted from it. The exhaustion and the syncopes which the ancients expected to prevent by acting in this manner, are still more effectually prevented by means of a bandage suitably applied, and patients, after having submitted to this operation, would be poorly satisfied if their belly was but partially emptied.

V. *Dressing.*—*The compressing bandage after the puncture*, not only has the advantage of supporting the viscera, but is also a powerful auxiliary in effecting a radical cure. The authentic facts in support of this assertion are now sufficiently numerous to induce us to add to their number more and more. In the spring of 1831, I was

desired by M. Rousseau, a physician at Batignolles, to puncture the abdomen in a child five years of age, affected with ascites during the previous 8 months. We withdrew six litres of limpid water from the abdomen. No alteration in the viscera could be recognized through the walls of the belly. A methodical and gentle pressure was immediately applied; the effusion was not reproduced, and the little patient soon recovered its former health. M. Fenoglio. (*Gaz. Med.*, 1832, p. 588, 589,) in operating on a woman 22 years of age, whose belly contained 36 pounds of water, and afterwards on a man aged 40 years, and from whom 40 pounds of serosity were extracted, succeeded equally well in both cases. The manner of applying compression in such cases, must be left to the discretion of the operator. Whether we make it with a flannel band, as recommended by M. S. Cooper, after the advice of Bell, with Monro's bandage, or with a sort of lousange terminated in a scapulary above, and by infra-crural bandages below, in such a manner that it may be conveniently tightened transversely; or make use simply of a body bandage, and compresses or other napkins folded in various ways upon the hypogastrium and flanks; provided the compression is methodical and regular, the rest is a matter of little importance. Large temporary blisters after the puncture in patients who cannot support compression, would probably afford more chance of success than before the operation.

VI. *Injectiōns*.—Some persons think that the radical cure of ascites might be accomplished after the puncture, by adopting another method. Noticing what happens in hydrocele, they have proposed to throw up into the peritoneal cavity irritating liquids, in order to favor its adhesive inflammation. Brenner, who appears to have been the first to make this suggestion, and who had no other object than to give tone to the viscera, proposed a solution of camphor, aloes and myrrh in *brandy*. Warick made trial of it and cured his patient. Repeated with *red wine and tar water*, these injections were not attended with the same success, and the two women died. Warrick, after having made trial of the process of Hales, who recommended that a canula should be placed on each side of the belly, in order that the liquid might be enabled to run out of one while the injection was thrown up through the other, ultimately gave a preference to Bristol waters and simple puncture. Though since recommended by Heuermann, Bossu, and others, injections in ascites were wholly proscribed, until a few years since the annals of Broussais brought to their support two cases of success obtained by means of the vapor of wine. M. Lhomme, (*Arch. Gén. de Méd.*, t. XIII., p. 282,) emboldened by these examples, ventured to make trial of the same process in an adult who had already several times undergone puncture. The result exceeded his hopes. His patient, as well as that of M. Gobert, and that of M. La Faye, (*Lancette Franc.*, t. II., No. 88,) continues to enjoy excellent health. A question of so serious a character, requires more conclusive facts before it can be solved. There is nothing to show that M. Lhomme actually caused the *vapor of wine* to pass into the belly. He filled, he says, a syringe with it, but the linen wet with cold water, and with which he thought it necessary to wrap the canula, through which the vapor had to pass, must have necessarily condensed it immediately; so that very probably it was air, and not wine, injected

into the abdomen. The patient operated upon with it by M. Dupuy, (*Arch. Gén. de Méd.*, February, 1832, t. XXVIII., p. 271,) died. The cases of M. Jobert, (*Lanc. Franc.*, No. 70, 73,) like those of Heuermann, Litre, Garengeot and Bossu, appear to have reference only to encysted dropsies, or not to have been followed by a radical cure, while those of Warrick are too imperfect to claim any great degree of confidence. The patient cured by M. Vassal, (*Soc. de Méd. Prat.*, 1833, No. XII., p. 8,) by means of puncture, massage and irritations with the beak of a canula of a trochar, was followed by too many serious accidents to embolden practitioners to make trial of the remedy that saved her life. Nevertheless, it is not improbable that we may succeed ultimately in obtaining from these trials an important point in practice.

Reasonings based upon numerous facts induce me to believe that the cure of ascites only takes place by means of adhesion of the parietal lining of the peritoneum with the abdominal viscera. The colics which those who have escaped from this disease habitually experience, and the disturbance that they are troubled with in their digestive functions, would constitute the proof of my assertions. A man about fifty years of age, cured of an ascites fourteen years before, and who died of pneumonia at the Hospital of Tours, in 1817; and the young girl nineteen years of age, cured at fourteen years of age of a similar dropsy at the Hospital des Enfants, and who died in consequence of a cerebral lesion in 1824 at the Hospital of Perfectionnement, had both of them all the intestines glued together and to the walls of the abdomen by innumerable cellular lamellæ and filaments. Such being the fact, it remains to ascertain whether prudence and humanity would authorize us to imitate, under these circumstances, the processes of nature. With a view of elucidating this fact, M. Bretonneau and myself, in 1819, made some experiments upon dogs. We injected into their peritoneal cavity, first pure water, then brandy diluted with water, and finally water strongly impregnated with muriate of soda; but no inflammation could be excited in these animals, and all the liquids injected were absorbed at the expiration of a few days. A patient in whom there was no hope of effecting a cure by the usual remedies, and who was threatened with immediate death, was submitted to the same experiment. He died, but in consequence of his dropsy and from a portion of the liquid which had become effused into the substance of the walls of the belly having caused there a gangrenous erysipelas. M. J. Cloquet has frequently mentioned to me a patient in whom a vinous or alcoholic injection for congenital hydrocele had, contrary to his intentions, passed into the abdomen, but who nevertheless after some unpleasant symptoms was ultimately cured. Without wishing to deduce from those various trials conclusions which are not tenable, I nevertheless think them worthy of attracting attention. They go to show at least that injections into the peritoneum are not as formidable as is generally supposed, and that before passing upon them an absolute condemnation, it would be advisable to make them the subject of varied experiments and of an impartial and profound investigation. M. J. V. Roosbroeck, (*Rev. Méd.*, 1832, t. I., p. 250,) having been struck with the diuretic and sudorific property of the

*gaseous oxide of azote*, (*gaz oxidule d'azote*,) concluded to inject it into the abdomen of dropsical patients after puncture. Three patients, a man and two women, submitted by him to this treatment, derived such advantages from it that Broussais in his turn ventured to make trial of it, but in a patient who was in so desperate a condition that it was surprising to find he survived it even the period of eight days. The author puts two gros of nitrate of ammonia in a glass phial, to which he adapts a bladder with a faucet: lutes this apparatus and places it over the flame of an alcohol lamp; allows the bag to become filled with gas by the decomposition of the salt; unlutes it and waits until the whole has cooled; places the extremity of the faucet in the opening of the canula of the trochar, and then immediately proceeds to injecting it. If there is no error in the account of M. V. Roosbroeck, there is no doubt that practitioners should be solicitous to repeat his trials, which M. La Faye has also found reason to be satisfied with. From what I have seen of *iodine injections* in hydrocele and serous cysts, I am induced to believe that they would afford much better chances of success than wine, in ascites and cysts of the abdomen.

VII. *A bladder of gold-beater's skin*.—A bladder of gold-beater's skin, in the manner it is applied in the radical cure of hernia, as proposed by M. Belmas, introduced empty, then distended or filled with a suitable liquid while it is in the peritoneum or cavity of the cyst, and maintained at the outside by its extremity—could it have, as the author thinks, the advantage of graduating the irritation at pleasure, and of even suspending it if necessary by enabling us to withdraw the foreign body which has produced it? I would not dare to hope for this result.

VIII. On the supposition that nothing of this kind has been done, and that the *effusion has reappeared*, the puncture must be repeated again and as often as becomes necessary, proceeding in other respects according to the rules laid down above.

There are patients in whom life may be thus prolonged for many years, and in whom we have to have recourse to it every two or three months. Dropsy of the ovarium, which is a purely local disease in most cases, is the one which supports these repeated operations the best. Partial or encysted dropsy has also, in certain cases, been unquestionably benefitted by it; but it is doubtful if general ascites can be classed in the same category, or continue after the operation of paracentesis so long a time without terminating fatally. Thus, when we find it affirmed that puncture has been performed 9 times on the same woman by Saviard, 11 by Litre, 29 by Grew, 57 by Cheselden, 47 by Laub, 86 in the space of 26 years by Martineau, 52 by Schmucker, 65 by Mead, 100 by Callisen, 187 by M. Roloff, (*Revue Méd.*, 1826, t. II., p. 148,) in a woman who performed it upon herself 62 times, near 200 times in another case, (*Journ. Univ. des Sc. Méd.*, t. III., p. 119,) and even 655 times by Bezard, (*Bull. de la Soc. Méd. d'Em.*, No. 12, Dec. 1812,) and that the fatal issue of this malady has been thereby procrastinated, it is next to certain that the cases under consideration were dropsy of the ovarium and not ascites, properly so called. It was in the case of an ovarian cyst

that I was obliged to perform it 37 times in one woman, and 29 in another in less than three years.

### § III.—*Operative Process.*

The various articles are composed of a trochar of two lines in diameter, armed with its canula and besmeared with cerate; a tub or any large vessel whatever suitable for receiving the liquid; a smaller and deeper vessel which can be held near the belly, if the serum does not run with sufficient force to render it unnecessary; a portion of adhesive plaster; various compresses folded several times; a napkin in the form of an ecusson; another napkin folded in a triangular shape and with infra-crurals and its scapulary attached. An assistant is stationed near the head, and one towards the feet and the side upon which the patient is laid, in order to support his chest and the upper part of the thighs. A third stationed upon the opposite side, or even on the bed, should he apprehend that he may be otherwise too much fatigued, holds himself in readiness to place his hands flatwise over the whole surface of the belly, in order to make gentle compression upon it in proportion as the liquid escapes. The surgeon seizes the trochar and plunges it with his right hand through the abdominal wall, the teguments of which he has kept stretched with his left. Forced in suddenly, and in an energetic manner, the instrument scarcely gives the patient any pain. Many authors, fearing that it might go too deep and wound some of the viscera, prefer introducing it gently while turning it upon its axis, and suppose that they escape still better by this means the danger of wounding any arteries. Arguments like these have no foundation. The organs of the lower belly are, as I have already said, too remote from its parietes in ascites, for the trochar to touch them, even though it should be plunged in up to its handle. Nor is there any greater necessity of obtaining a point d'appui with the two last fingers on the skin, while we are introducing it. Such precautions moreover are only calculated to render the operation more difficult and protracted. The forefinger or thumb elongated upon the stem of the trochar, while the palm of the hand firmly embraces the handle of the instrument, leaves naked only so much of it as we wish, and as is required for reaching the collection of liquid, and will secure us from wounding the viscera. Should the walls of the belly or cyst be one, two, or three inches in thickness, so much so in fine as to embarrass the operator, an instance of which Saviard states that he has met with; or should they be so flabby as to yield under its pressure, we would employ another instrument, and it would be under such circumstances that the bistoury or lancet might be substituted with some advantage. When there is no longer any resistance to the instrument, it shows that we have entered into the peritoneal cavity. The canula, which is to rest in its place with the mouth directed downwards, is held there by means of the left thumb and forefinger, while the trochar is being withdrawn from it. The liquid escapes immediately with more or less force, and with a jet which may then be readily directed into the tub destined to receive it. The blunt-pointed probe, chest sound, &c., are only useful in cases where some foreign body

has got introduced into the canula. All the water being extracted, the operator withdraws the canula by rotating it on its axis, and at the same time supports by means of the two first fingers of his other hand, the periphery of the aperture he has made, to prevent the skin from being drawn upon it; applies over this point the plaster, and compresses; in this manner dresses the whole front of the abdomen and the sides; adjusts the body bandage and immediately places the patient in the middle of his bed, and in the position which is least fatiguing to him.

#### § IV.—*Accidents.*

Hemorrhage occasioned by puncture, though a rare occurrence, is however the inconvenience which has most attracted the attention of practitioners. M. C. Smith has collected ten examples of it. It is easily arrested when it arises from a wound of the epigastric artery, or any other vessel in the parietes of the abdomen. Various means are used for this purpose; one of them employed in the last century as recommended by Petit-Radel, and which M. Cruveilhier states that he has made use of with advantage, consists in including a large fold of the soft parts in the track of the trochar, then compressing it, and even making friction upon it slightly with the thumb and forefinger until the blood has ceased to flow. A small *plug of wax*, the extremity of a *rat de cave* candle, cut in the form of a peg, as recommended by Bellocq, or what is better still, a piece of gum elastic or plastic bougie, such as we make use of for the urethra, inserted into the wound in such manner as to fill it up exactly, is a resource which in this respect appears to me to leave nothing to be desired. I do not know however if a piece of prepared sponge would not answer still better. This substance, by imbibing the liquid at the bottom of the wound, would evidently make compression outwardly in the most advantageous manner; but it would also possess the inconvenience of being liable to be broken when it was found necessary to withdraw it. If the blood, instead of escaping outwardly, should have accumulated in the interior, it would be difficult to recognize it before death. In supposing moreover the contrary case, the surgeon would not be benefitted by it. What could he do under such circumstances, and where could he go to seek for the deep-seated vessel which furnishes the hemorrhage? We must not moreover allow ourselves to be imposed upon by appearances. We sometimes meet with, upon the surface of serous membranes, a sanguineous exhalation so abundant as to communicate to the water drawn from a dropsical patient, the dark color of venous blood; so much so that at first sight we might be induced to believe that it was blood instead of serosity which was running from the wound we had made. A striking example of this occurred in an adult affected with hydrothorax at the hospital of St. Antoine, in the wards of M. Rayer, while I had charge of the surgical department in this establishment, and there is no doubt that the same phenomena might take place in the peritoneal cavity. The hemorrhage mentioned by M. S. Cooper as resulting from a puncture upon the median line, might well belong to this description. Upon the supposition that the one which was

noticed at La Charité, in 1824, was not produced by a pure and simple wound of the epigastric artery, it might also be explained in the manner I have mentioned much better than by the alleged lesion of a mesenteric vessel. M. Piegdagnel however relates an instance of a copious effusion of blood, caused, as he believes, by a puncture of an artery of the epiploon.

## ARTICLE II.—HUMORAL TUMORS OF THE LIVER.

Abscesses, hydatid cysts and encysted dropsy of the liver, have been for a long time, and are still regarded by many persons as placed beyond the reach of all surgical resources. The difficulty of recognizing them with certainty during life; the danger of producing an effusion into the peritoneal cavity, and allowing the action of the air on the walls of the collection, are the reasons why an artificial opening has been generally proscribed. There are, however, related instances of cures obtained by means of a puncture with the trochar, or by means of an opening made with caustic potash. On the other hand, the mode by incision having been the subject of special researches, and M. Récamier having succeeded in obtaining very fortunate results by combining those different resources, I have thought it proper to treat of them in this place in a separate article. Puncture alone would be insufficient should the cyst contain anything else than limpid serosity. Moreover, it would cause the effusion of a certain quantity of liquid into the belly, should there not have been established protecting adhesions around the part that is perforated. The employment of the bistoury would be still much more apt to give rise to the apprehension of this accident: it cannot be applicable except in cases where the diagnosis leaves no room to doubt the nature and anatomical relations of the cyst. Caustics, by acting too slowly, incur the risk, it is said, of general peritonitis, in consequence of the local inflammation which is produced by their application. A young lady, however, whom MM. C. Broussais, Sédillot and myself treated in 1838, by means of the free application of potassa, was perfectly re-established. In the process of M. Récamier, potash is first applied upon several points that are nearest to the morbid projection, in order that by their reunion they may make a large eschar, which is laid open at the expiration of a few days by means of the cutting instrument. Another portion of caustic is then applied to the bottom of the wound, and which is destined to act much rather in its depth than in its breadth. Repeated in this manner in succession, the cauterization is certain to promote the adhesion of the hepatic portion of the peritoneum with that of the abdominal walls, and enables us to plunge into the cyst either the trochar or the bistoury, as soon as the finger clearly recognizes the fluctuation underneath the incised eschar. After having extracted all the liquid, M. Récamier, imitating the practice of M. Billerey for empyema, substitutes for it *medicated injections*, which he renews every day, and which he retains in the morbid cavity, in the intervals between the dressings, by shutting up the wound with a pledget of lint or sponge. By this means the action of the air is prevented, the pus, diluted as soon as it is produced, cannot stagnate or pass into a pu-

trid state in the interior of the abscess, and the sac gradually shrinking upon itself, ultimately becomes transformed throughout its whole extent into a simple fistula, which, in its turn, may be healed up. Can it be necessary to add, that the same treatment is applicable to tumors in the *gall bladder*, as soon as they are placed under the conditions laid down and so well described by J. L. Petit? To elucidate the diagnostic in all the affections under consideration, we are frequently obliged to make an *explorative puncture* by means of a small trochar or cataract needle, in the same way, for example, as when we wish to distinguish with certainty between an aneurism and an abscess. M. Récamier justly remarks that, in this case, the instrument should be very delicate, and suddenly withdrawn from the tissues. Unless this were done it might make a wound which would give ready egress to the liquid, in such manner as to cause it to be effused into the abdomen or in the surrounding organic tissues. Another mode of opening into morbid collections of the liver or abdomen, and which was proposed in 1827 by M. Graves, (*Arch. Gén. de Méd.*, t. XVIII., p. 295,) is worthy of being placed alongside of the preceding. This surgeon employs the bistoury only. After having freely incised all the tissues, as far down as to within one or two lines of the abscess, he stops and fills the wound with lint, and waits until the tumor shall open of itself, at the bottom of the wound, during a paroxysm of coughing, &c. M. Bégin (*Journ. Hebdom.*, 1830, t. I., p. 417,) has since proposed, for all purulent abdominal collections, that we should proceed in this manner, layer by layer, down to the peritoneum, and stop there should there be no adhesion, but, in the contrary case, to penetrate into the cyst. Should the tumor be still free, the wound of the peritoneum, which it immediately tends to fill up, speedily agglutinates with its anterior surface, and three or four days after we may plunge in the instrument in this part without any danger to be apprehended from effusion into the belly. Facts, sufficiently conclusive, have been related in England and in France, in favor of this ingenious method, and I have had recourse myself to it in three instances with advantage.

### ARTICLE III.—CYSTS AND TUMORS OF THE OVARIUM AND OF THE LOWER BELLY.

*The ovarium* is frequently the seat of a degenerescence, which has been pointed out by authors of every epoch, but for which no one scarcely proposed to procure relief by means of a cutting instrument until about a century since.

#### § I.—Appreciation.

Le Dran, Housson and Garengeot had already remarked that puncture scarcely ever succeeds in this affection, while it is sometimes cured by freely incising the cyst. The patient of M. Holscher (*Arch. Gén. de Méd.*, 1838) was cured after puncture, by means of an injection of two litres of wine. Morand maintains that extirpation of the diseased organ should be performed at the very first.

*A. Successful Results.*—Facts communicated by Delaporte and Lieutaud were adduced in favor of this operation, the process of which had already been given by Thumin, and which two English physicians, Power and Darwin, hastened to advocate with zeal; but in spite of the efforts of M. Ischier, (*Thèse de Montpellier*, 1807,) the successful result attained by Laumonier, the cure of Mme. de Choiseul, and the similar result related by M. Kapser, the proposition of Morand, nevertheless, remained without any adoption in practice, until M. Lizars (*Bull. de Fér.*, t. IV., p. 141,) undertook to recall attention to it in 1825, while on their part MM. McDowell, Nathan and Alban Smith, (*Journ. des Prog.*, t. V., p. 273,) made trial of it in America, and MM. Dieffenbach, Chrysmer (*Bull. de Fér.*, t. XVIII., p. 86,) and Martini sought to render it popular in Germany. At the present day the operation has been performed a sufficient number of times to enable us to appreciate the extirpation of the ovaries at its just value. Leaving aside the operation as formerly performed by Lemman, the one published by M. Lafflisse of Nantes, and another which belongs to Delpech, I will confine myself to an enumeration of the most important cases. The tumor removed by M. McDowell from Mrs. Crawford in 1809, weighed 15 pounds, and the cure was completed on the 35th day. In another patient, M. McDowell finding both ovaries affected, made his incision upon each; a quantity of blood was effused into the belly, but the operation, nevertheless, was attended with entire success. In 1816 he removed an ovary from a negress, which weighed six pounds, but which was also followed by a perfect cure. Two other women whom he treated in the same manner were not so fortunate; one remained in feeble health and the other died. Dzondi in one instance succeeded by means of an incision, the employment of tents, and afterwards by extirpating the mortified cyst. Pure and simple extirpation performed in a case in 1821 by M. Smith, was not followed by any accident. The tumor removed by M. Lizars on the 27th of February, 1825, was as large as a fœtus at the full term. It became necessary to prolong the wound of the belly from the xiphoid appendix down to the pubis. The other ovary was also affected, but the patient, who was 36 years of age, nevertheless ultimately recovered. Dr. Chrysmer, sent for to a woman 38 years of age, had every reason to be satisfied with his resolution to perform the operation: at the expiration of six weeks the patient was in a condition to return home. M. A. Smith operating on the 6th May, 1822, on a young lady, extracted the cyst after having taken six pints of liquid from it, and after having strangulated it at its base by means of a strong ligature, which came away at the expiration of a month and a half. In 1824 this lady was still in the enjoyment of the most perfect health. M. Jeaffreson (*British Annals of Med.*, vol. II., p. 140,) incised the cyst, extracted twelve pounds of serum, drew it outwards and extirpated it, and also cured his patient. M. King (*Ibid.*, vol. II., p. 141,) obtained a similar successful result. In the case of M. Weitenkampff, (*Encycl. des Sc. Méd.*, 1836, p. 312,) a spontaneous opening in a similar cyst into the vagina was also succeeded by a cure. M. Quittenbaum, (*Ibid.*, p. 306,) in extirpating the tumor, after having extracted from it 20 or 30 pounds of liquid

by puncture, even alleges that he effected a cure of his patient in the space of ten days! After numerous punctures, M. Rogers (*New York Med. and Phys. Journ.*, 1830, p. 285,) extirpated the cyst and succeeded. The same result followed in the case of M. Ehrharstein, (*Arch. Gén. de Méd.*, t. I., p. 427; *Méd-Chir. Rev.*, July, 1833, p. 242,) who removed in this manner a degenerate tumor of the ovary, and in that of M. Ritter, (*Tahère Thèse*, No. 85, Paris, 1839,) who was no less fortunate.

B. To these cases of actual extirpation, followed by a successful result, we have to add others in which the tumor was not entirely removed, and where the operation was not completed in the manner proposed before commencing it. It was in this way for example, that M. Lizars, finding a simple adherent mass in front of the sacro-iliac-symphysis, instead of an enormous cyst as he had at first supposed it to be, deemed it proper to restrict himself to the first stage of the operation, that is, to the incision of the parietes of the abdomen; immediately closing up the wound, he considered himself sufficiently fortunate in saving the life of his patient. In another case, M. Granville, (*Journ. des Progr.*, t. I., p. 274,) perceiving that the cyst could not be detached from the surrounding parts without difficulty, confined himself to laying it open freely, and carefully emptying it. By this course he obtained complete success. M. Dieffenbach, alarmed by the size of the base of the tumor, and of the vessels it contained, and seeing moreover that blood only issued from a puncture made in its centre, did not venture to remove it, and immediately united the wound, when the patient also recovered.

M. Galenzowski, (*Journ. des Progr.*, t. XVIII., p. 222,) also perceiving that the tumor was too adherent to be removed, emptied it by a large opening, broke up its different cells, traversed its deep-seated wall with a thread, drew it towards the wound in the abdomen to prevent all effusion into the peritoneum, closed up in the best manner he could the incision in the abdominal parietes, and obtained in this manner a perfect cure in the space of a few weeks. M. Mussey, (*Gaz. Méd. de Paris*, 1838, p. 393,) who after having freely incised the walls of the abdomen, confined himself to the puncture of the cyst, and afterwards the employment of a meche, also succeeded. M. King, (*Press. Méd.*, t. I., p. 634,) who, deterred by the fainting of the woman in one case, and from not finding in another any tumor in the belly when he had introduced his hand there, closed up the wound by suture and had no serious accidents follow! M. Dohlhoff, (*L'Expérience*, t. I., p. 634,) after having made an incision of five inches, and finding no description of tumor, also closed up the wound and saved his patient!

C. *Failures*.—Other trials have been less fortunate. A woman 40 years of age, operated upon on the 20th September, 1822, by M. McDowell, died on the morning of the 24th. M. A. Smith, deterred by the intimate and very extensive adhesions of a tumor of the ovary, in a patient who herself had punctured it more than 80 times, restricted himself to the incision of the walls of the belly, and did not dare to terminate his operation. He had the misfortune, however, to see this lady perish on the 42nd day. The patient operated upon by M. Lizars on the 22nd March, 1825, died on the second day

after. The one which was operated upon by MM. Hopper, (*Bull. de Fér.*, t. XVIII., p. 86,) and Chrysmer, survived only 36 hours. Another operated upon by M. Chrysmer himself was not less unfortunate. The young girl whose case is given by M. Martini, also died at the expiration of 36 hours. The patient operated upon by M. Warren, died at the end of three hours, and M. Dohlhoff, (*L'Expérience*, t. I., p. 625, 626,) who, though the special pupil of M. Dzondi, never heard him speak of the successful results that M. Lizars imputes to him, speaks: 1st, of a woman operated upon by him, and who died of peritonitis in 36 hours, (*Ibid.*, p. 630;) 2nd, of a female operated upon by M. Grath, (*Ibid.*, p. 631,) who died from hemorrhage at the expiration of sixteen hours; 3rd, of another in whom he opened the belly, and who had the epiploon cribbled with tumors, and who died eight hours afterwards, (*Ibid.*, p. 633,) without of course the operation being carried any farther. M. Key, (*The Lancet*, 1828, vol. I.,) in a case in which he employed puncture and a tent, did not succeed. M. Kapser obtained only one cure out of three cases. A woman in whom the cyst was of the size of the uterus in the eighth month of pregnancy, and in which M. Récamier (*Revue Méd.*, January, 1839,) made a puncture in order to introduce a meche or seton from above downwards through the vagina, also died. M. Marjolin, (*Thaëre Thèse*, No. 85, Paris, 1839,) who confined himself to an injection of sweetened barley water, was no less unfortunate.

**D. Real Value.**—Extirpation of the ovary, though dangerous, is nevertheless a resource which requires examination. The ovary is not so indispensable to the existence of life that a woman cannot be deprived of it without very great danger. The gelders of beasts remove them without any apprehension during the first weeks of the life of the animal, in the female of the hog, and I am enabled to assert that in their hands this operation is scarcely ever followed by any accidents. Diemerbroeck relates, that according to Atheneus, Adrametes, and according to Suidas, Gyges, king of Lydia, treated the women in their kingdom in this manner. Alexander-ab-Alexandro says the same of the Creophagi and the Egyptians. Wierus states that a gelder suspecting the chastity of his daughter, opened her belly, and drew the womb to the outside in order to excise the two ovaries, and that this cruel operation was followed with complete success. Franckenau, Pott, Lassus, (*The Lancet*, 1828, vol. I., p. 878,) and M. Deneux, each relate an instance of extirpation of the ovary, which did not prevent the females from afterwards enjoying excellent health.

*In conclusion*, the operation is not in itself either delicate or difficult. The occasions for performing it are unfortunately but too frequent. The diseases which require it, if left to the resources of the system, almost always terminate in death. But also, in order that there should be any chance for success, it is necessary that the tumor should be movable, that it should not adhere to the intestines, that it should be susceptible of being detached with facility from all the abdominal organs, that it should have a root or pedicle of small size, and that it should not expose to the risk of wounding vessels of too large a calibre. It is necessary also, that it should be susceptible of being

recognized and distinguished from every other disease, which is far from being always an easy matter. In the beginning, how can we avoid confounding it with some tumor or other attached to the uterus, the iliac fossæ, &c.? Moreover, who would then dare to propose to extirpate it? At a later period, when it occupies a large extent of the abdomen, the new relations contracted by the organs which surround it, and the almost inevitable adhesions of its periphery, would render its dissection and ablation, if not impossible, at least exceedingly dangerous. Finally, though incurable in its nature, it does not generally cause death until after a long protracted period. As a medium term, its duration is usually prolonged, not to 12 years, as M. Corbin thinks, but 5 or 6 years in women who are affected with it. Nevertheless, if as happens often in such cases, the general health has been preserved in a manner which contrasts strongly with that of the diseased condition of the abdomen; if the issue of an unctuous or gelatinous liquid obtained by means of an explorative puncture, demonstrates that the disease is situated in the ovarium; and if the tumor does not exceed the size of the head of an adult, and the patient ardently desires the operation, it ought in my opinion to be undertaken. Only that it remains to determine if the simple incision according to the rules laid down in the preceding article, made trial of by Portal and Denman, (whose cures however are doubted by M. Key,) and by MM. Ray and Ramsden, who have also, it is said, each obtained a cure by this mode, ought not to be preferred to extirpation, properly so called.

## § II.—*Operative Process.*

The woman placed upon her back, with her lower extremities moderately extended and held by assistants, should be adjusted in such manner that the most prominent portion of the cyst presents itself to the operator. This last first makes, in a direction parallel to the axis of the body, an incision from four to six or eight inches long upon the most suitable part of the abdomen, makes use of the forefinger of his left hand to guide the bistoury, as soon as the peritoneum is opened, and then occupies himself with the tumor. Should it be free and movable, and easily isolated, and have a narrow pedicle, the surgeon has nothing more to do than to tie a ligature firmly around its root, and to excise it upon the outside of the constriction by means of the bistoury or scissors. Should the adhesions which unite it to the surrounding tissues be loose or easily destroyed, he detaches them by means of a careful dissection, and proceeds in respect to the remainder of the operation as in the other case. Should it prove to be fungous, and to have a large base and blood-vessels of considerable size, it would be better not to meddle with it and to close up the wound immediately. Should its adhesions to the wall of the belly not admit of its removal, we should plunge the bistoury into it, and lay it open freely in such manner as to empty it entirely, and that the cyst may afterwards be gradually drawn into the wound of the abdomen. The position, adhesive plasters or the suture will be used according to the nature of the cases, to reunite the wound, which moreover should be dressed in the simplest manner possible. When

the solution of continuity has been very extended, the intestines have so great a tendency to escape externally, that the suture then becomes almost indispensable. The same takes place nearly in all cases, where in order to remove the tumor, it has not been necessary to lay it open, nor to occasion any very great destruction of parts in the interior of the belly. It is directly the reverse when we have only emptied the cyst, or have not had it in our power to extract all that we wished to remove. Upon the supposition that we purpose to confine ourselves to the incision, it would be necessary to put ourselves on our guard at first, against effusion, and to encourage the previous formation of protecting adhesions, if they did not already exist, between the morbid mass and the parietes of the abdomen; and finally, to act in the same manner as in the case of an abdominal abscess or hepatic collection.

#### ARTICLE IV.—TUMORS OF THE ABDOMINAL PARIETES.

M. MacFarlane, (*Encyclog. de la Sc. Méd.*, 1836, p. 54,) who states that he has removed with success an hydatid tumor in the iliac region, was less fortunate in two other cases. Entering through the puncture into a cyst, between the peritoneum and the muscles, death took place on the fifth day. Compelled to remove the ends of the two last ribs with a fibro-cartilaginous tumor which had become developed between the muscles, he had the misfortune to lose this patient by peritonitis at the expiration of thirty-one hours. In the case cited by M. Basletta, (*Bull. de Fér.*, t. X., p. 95,) the removal of the cyst, containing a pulpy substance analogous to that of the testicle, and which communicated with the peritoneum, was followed however by the cure of the patient. It was the same with the cyst in the case mentioned by M. Dufau, and which burst during an effort made by the patient. M. Monod has shown me a neuromatic or atheromatic mass of the size of a large fist, which he had successfully removed from between the abdominal muscles; but I have mentioned, under the chapter on tumors in general, and of tumors of the abdomen in particular, what ought to be the special operative process in cases of this kind. The important indication is to avoid the peritoneum. Should it have become necessary to wound this membrane, we must be guided by the rules laid down for the operation for strangulated umbilical hernia, the Cesarean operation, or that employed in cases of cysts of the ovaria, &c.

[*Ovariectomy*.—The results of the latest researches and examinations of comparative statistical tables on this subject, as furnished by MM. Jeaffreson, (*London Med. Gaz.*, October, 1844,) B. Phillips, (*London Medico-Chir. Trans.*, vol. XXVII., 1844,) Chereau, (*Journ. des Conn. Méd.-Chir.*, Juin, 1844,) F. Churchill, (*Dublin Journal and Archiv. Gén.*, 4e série, t. V.) and Emiliani, (*Giornali dei Progressi*, January, 1845,) seem to admit of our establishing the following conclusions, deducible from about *one hundred* cases in which the operation has been performed, up to the present year, 1846, (see *Archiv. Gén. de Paris*, Février, 1846, 4e série, t. X., pp. 216—219.)

1. That the operation is practicable, and even easy, in most instances.
2. That it has received unmerited reproach, in consequence of enu-

merating under its failures those cases which have been abandoned, and in which the operation has been left unfinished, from the operator having ascertained that his diagnosis was false and the adhesions too extensive, (see Jeaffreson, *supra cit.*) 3. That the most favorable indication for it is the existence of liquid, and especially *monolocular* tumors, in which the whole contained fluid may be readily evacuated by paracentesis as often as it forms, but which therefore, for the same reason, are those in which it is least called for. The next most favorable, and where, however, it is at the same time most required, are the *multilocular* liquid tumors, because here the puncture can have but little, at least only a partial and temporary effect. Again, it is in a great measure contra-indicated, and ought to be forbidden, as we think, in solid or sarcomatous or fibro-cartilaginous ovarian tumors, from the very extensive nature of their adhesions. Nor do we except, with Dr. Jeaffreson, from this remark the cases where such tumors lead to consecutive ascites, threatening a fatal issue. 4. The larger the incision, the less the chances of cure; and the smaller the incision, the more the prospect of a successful issue, even though to facilitate this last, the cyst has to be punctured before it is extracted. 5. The proportion of deaths is in the ratio of 49 out of every 100 cases operated upon, i. e. 49 deaths and 51 cures, which is a relative mortality not much greater (*Arch. Gén.*, *ibid.*, *loc. cit.*, t. X., p. 219,) *than that of amputation of the thigh*. But we are to deduct in part from this estimate, and in favor of the operation, the fact, that in 18 cases out of the 100, the operation had to be abandoned, which of course, in some degree, augmented to the same extent the chances of a fatal issue; while, on the other hand, there was a *false* diagnosis in 7 out of the same 100 cases. 6. That so far from adopting the precept of Dr. Jeaffreson, that the operation may be *justifiable* where the size of the tumor gives rise to great annoyance or inconveniences, or to such functional derangements as threaten a fatal issue, we do not think that it would even then be admissible, except under very peculiar and very unusual circumstances. 7. That, on the contrary, we coincide with the reviewers of the *Archives Générales*, (t. X., *loc. cit.*, p. 219,) in language which seems also wholly congenial with the text of our own author: that the *extirpation of ovarian cysts*, though it cannot be absolutely rejected, can be had recourse to only in cases that are wholly exceptional and excessively rare, and where every other known therapeutic means has been exhausted. T.]

#### ARTICLE V.—FISTULAS IN THE STOMACH, (Fistules Stomacales.)

Having elsewhere spoken of foreign bodies in the abdomen, and having yet to speak of gastrotomy and stercoral and urinary fistulas in the chapters which are to follow, I have but a few words to say in this place on the subject of stomachic, biliary or renal fistulas. An instance of stomachic fistula has been published by M. Stokes. (*Arch. Gén. de Méd.*, 2e série, t. VI., p. 430,) and M. Beaumont (*Journ. de Prog.*, t. XII., p. 254,) has related another. M. Lowel (*Bull. de Fér.*, t. VI., p. 157,) states that he saw a similar result in one of his patients, produced by a gun-shot wound, and M. Cook, (*Arch. Gén. de Méd.*,

2e série, t. VI., p. 430,) alleges that he cured one in fifteen days by means of compression; but I am not aware, up to the present time, that the slightest operation has been attempted for this description of fistulas, which, moreover, are quite uncommon. We might, however, I think, have recourse, with some prospect of success, either to the simple suture or to one of the modes of anaplasty described elsewhere, and which I shall recur to in treating of artificial anus. As to biliary fistulas, an instance of which has been given by M. Civiale, (*Gaz. Méd.*, 1832, p. 130,) and renal fistulas, of which I have met with three examples, they are produced either by calculi, or some other lesion either of the gall-bladder, or of kidney or its pelvis (*bassinet*,) which must first be relieved before we proceed to their treatment.

## PART FIFTH.

### HERNIA.

#### CHAPTER I.

##### HERNIA IN GENERAL.

##### ARTICLE I.—ANATOMICAL REMARKS.

A hernia, of whatever description it may be, presents two points for consideration,—its envelopes, and the viscera which constitute it.

##### § I.—*Viscera.*

There is no organ in the belly which may not, under certain circumstances, form a hernia. They are not all of them, however, equally liable to strangulation. Thus the bladder, ovaria, uterus, spleen, and liver, have been seen either together or separately in a hernial tumor. But it can scarcely be conceived that these various organs are of a nature to undergo strangulation. An intestine, on the contrary, as soon as its calibre is interrupted in any point whatever, must necessarily give rise to many serious symptoms. The constriction of the epiploon does not, however, admit so ready an explanation of these phenomena; but whether this depends upon tractions made on the stomach and large intestine, or upon a sympathetic reaction transmitted through the branches of the trisplanchnic nerve, experience has shown that they may be developed under such circumstances, and that this fact must be admitted.

##### § II.—*Envelopes.*

The coverings in every hernia comprise as their essential elements, the integuments, the sac, and the intermediate layers. The skin presents nothing remarkable, except in relation to its different conditions of thickness, density, and adhesions. It is entirely different with the sac.

A. *Sac*.—The name of sac is given to that portion of the perito-

neum, which is protruded by the viscera outside of the belly, and which forms the first covering of the hernia. The ancients had very confused ideas upon this subject. They supposed that the descents or *hargnes*, (hernias,) which they also called on that account *ruptures* or *rompures*, were produced by means of a laceration of the peritoneum. At the time of Dionis, it is true, this error no longer existed, and the existence of the hernial sac was already admitted in the majority of cases; but it was not until the time of Mauchart and Arnaud, about the middle of the last century, in fact until the time of the Academy of Surgery, that the sac was considered an integral part of every description of hernia, so that at the present day its presence is always deemed essential.

I. I am in an error, for the *moderns* acknowledge that hernias resulting from wounds penetrating into the abdomen, the Cesarean operation, a ligature upon the iliac arteries, and gastrotomy, may in general be destitute of this sac. Nor does a hernial sac exist when the bladder is displaced at its anterior surface, or the cæcum upon the part at which it is adherent. This is a fact which M. Colson of Beauvais has demonstrated in opposition to the opinion of Scarpa, who entered into a long discussion to prove the contrary. We will remark, however, that under this last point of view, it is rather a dispute about words, than a real difference of opinion. Scarpa, in maintaining that cæcal and vesical hernias possess a sac, only wished to say in fact, that a greater or less extent of the displaced organ remains free in the tumor, and that a prolongation of the peritoneum is found there as well as in ordinary hernia. But M. Colson does not pretend to deny this arrangement; he alleges only, that inasmuch as the hernia is adherent in the greatest extent of its surface, we cannot give the name of sac to the portion of peritoneum which covers the remainder of it. Some persons, on the other hand, consider that hernias which are caused by traumatic lesions of the abdomen, have a sac as well as the others, unless they are not protruded before the complete cicatrization of the wound of the peritoneum. It is a question, however, which does not appear to have been considered in a correct point of view.

II. When a *perforating wound* closes up and is cured, there is ordinarily produced by it a cicatrix, which has less thickness, and is less resisting than the natural walls of the abdomen. The explanation of this is not that the two lips of the peritoneum are not reunited, but because, in place of muscles and aponeuroses, there exists in this part only a fibro-cellular tissue of new formation. If then a hernia should be formed here, whether it protrudes the cicatrix before it, or does nothing more than to displace it, in order to arrive externally, we cannot perceive how it can fail of being surrounded on every side by the peritoneum, and of possessing a true sac. But this cicatrix may to some extent remain independent of the serous abdominal layer, as it may happen that the peritoneum may have adhered so closely to the borders of the wound, which allows egress to the viscera, that the hernia shall have no sac.

III. What takes place in this case is also noticed at the *umbilicus*. I am perfectly satisfied, from dissections, that umbilical hernias (exomphales) do not usually have an internal tunic which can be separated

from the other envelopes. The smooth layer (*la couche lisse*) which has been taken for this, is intimately united with the external tissues, and has been developed by dilatation, and not by displacement of or traction upon the peritoneum. These facts authorize me to establish: 1st, either a *true* sac by transposition of the peritoneum; 2d, a *false* sac by simple *distension* of this membrane or of any other description of cellular tissue; 3d, an *incomplete* sac in vesical, and in cæcal and hernias, &c.; that is to say, that the hernial pouch is lined throughout with a true serous *membrane*, in the vast majority of cases, in some others but partially only, and that in a very small number what we see in its interior is only a simple surface in place of a *membrane*.

IV. The form and size of the sac vary in an almost infinite degree. Hemispherical, globular, pyriform, bosselated, conical, cylindrical, bisacculated, with a duplicate, triplicate, or quadruple neck, &c., it may scarcely exceed the size of a small nut, or be as large as that of the head of an adult. Its *internal surface*, which is smooth and moist, does not differ from that of serous membranes in general. Its *external surface* requires a little more attention. In the true sac it is lined with a cellular layer, which necessarily plays an important part in the history of hernias. Being a portion of the *internal fascia superficialis* or of the *fascia propria* of the peritoneum, this layer exists everywhere, but under different conditions of laxity, thickness and adhesions, which are exceedingly dissimilar upon various points of the abdominal cavity. It is in this that we meet with the vessels which are generally referred to the peritoneum, and it is this membrane which, by its induration or gradual thickening, produces what is called the epaïssement of the sac, and which, after having undergone a filamentous or semi-fibrous transformation, gives rise, when it is torn, to the bosselated or irregular appearance presented upon the external surface of certain hernias, and it is this membrane also which may be the seat of inflammations, suppurations or morbid alterations of every kind. From this in fine come the great majority of vessels which ultimately terminate beneath the skin after having traversed the muscles and aponeuroses, and it is this membrane upon which are found those small adipose masses which gradually escaping through the vascular orifices of the fibrous or muscular layers of the walls of the abdomen, ultimately, in certain cases, produce a projection under the integuments and lead to the erroneous supposition of the existence of hernias, properly so called. Around a false sac this layer intimately blended with the surrounding lamellæ, distinguishes it from the preceding, and is so constituted that in place of a membrane which may be *isolated*, it presents only a surface wholly incapable of being detached. The name of *neck* which is given to the portion of sac which is confined in the hernial opening, might be advantageously replaced by that of *root*; for the first involves the idea of a *strangulation*, which is far from always existing, while the second, which is equivalent to the word *origin*, would in all cases precisely express the thing intended. The neck of the sac then, and I speak of the true sac, and which is generally narrower than the body and bottom of this pouch, is quite frequently folded or gathered up like a purse in the ring which encloses it. Should the hernia be ancient or the folds have remained a long time in contact, it is readily conceived

that they might become agglutinated and impart to the neck under consideration, a considerable degree of thickness and resisting force.

V. The existence of several necks in one hernia, which had already been sufficiently well explained by Arnaud, and afterwards by Pelletan and Scarpa, is no longer a matter of obscurity or surprise since the labors of M. J. Cloquet. Suppose that a hernia, after having been a long time reduced, should afterwards reappear, and that the neck of the first sac being too narrow to give passage to the viscera, shall have been protruded by them at the same time that they draw down another portion of peritoneum and give rise to the formation of a new neck; should the same thing happen a second, third or fourth time, we shall have produced a sac in the shape of a chaplet with numerous necks. When the first adheres strongly by a portion of its periphery to the neighboring tissues, it is possible that the other may only cause that to deviate, in place of forcing it to descend before it. In this *double sac (bissac)* the two pouches are in front or by the side of, and not below each other. The production of such necks is also possible where the hernia has not been reduced. This then constitutes a new protrusion, which is situated above the ancient one.

VI. The *adhesion of a cord* or of a portion of the epiploon to the bottom of the primitive sac, is one of the most favorable circumstances for the formation of a second neck. Pelletan mentions a case in which the epiploon traversed in this manner three contracted passages, in order to fix itself to the bottom of the lower sac. I have met with an instance in every respect similar, another in which the upper sac also contained a noose of the intestine, and in 1832 another still at La Pitié, which scarcely differed from the first. As to the numerous necks of bosselated sacs, they are formed in a manner altogether different. These latter are simple hernias of the sac, through lacerations of the *fascia propria*, or of any other fibrous layer which should have taken its place. The sac, instead of necks, may be divided by actual septa and form one or more independent cysts below that portion which continues to retain the viscera. A striking example of this I saw in the patient operated upon by the process of M. Belmas.

B. *Aponeuroses*.—The tissues which separate the sac from the cutaneous layer necessarily vary according to the seat of the hernia, and could not be studied with advantage except in each particular hernia. I have therefore no occasion to speak at the present time of any other than the common cellular tissue and the superficial or *sub-cutaneous fascia*. When there are neither aponeuroses nor muscles interposed, the *fascia propria* and the *fascia superficialis* ultimately become blended in the thickness of the hernial pouch; that is to say, that we can no longer distinguish any separation between the cellular lining of the skin and that of the peritoneum.

C. *Hernial Openings*.—The openings which allow of the formation of abdominal hernias are of various kinds. Some which are accidental lacerations, as occurs in persons in whom the belly has been excessively distended by pregnancy, ascites or any tumor whatever, &c., rarely give rise to strangulation. The same remark is applicable, in a great extent, to those which result from a penetrating wound of the abdomen.

There are others also which do not require any farther consideration. The orifices which are here and there found upon the different fibrous layers of the oblique or transverse muscles for the passage of vessels of the third order are of this description, and present moreover this remarkable feature, that the masses or adipose tumors whose pedicle they embrace, and which augment in size under the skin and in the other direction are attached to the peritoneum, may dilate these openings and by degrees draw a portion of the peritoneum into them in the form of a sac or finger of a glove, in which the intestine in its turn may ultimately become lodged or even strangulated, and thus constitute a description of hernia which is very embarrassing to the practitioner who shall not have been aware of its possibility.

Those which it remains for us to speak of are arranged under two orders: these are either simple *openings* or *rings*, or passages of greater or less length and obliquity, and very generally known at the present day under the name of *canals*. At the umbilicus, for example, the opening is always annular, while at the fold of the groin it is generally canaliculated.

I. *Rings*.—The first species is not met with except upon those points of the abdomen where the aponeuroses and muscles do not form distinct layers, as at the linea alba, upon the side, and at the vagina, rectum, &c. From these parts, in fact, being incapable of becoming separated, and admitting only of an opening for the passage of the viscera, the hernia arrives under the skin immediately after having passed through them, and escapes in reality only through a simple circle before it is formed.

II. *Canals*.—The second kind of hernial opening is more complicated. Its internal and its external extremity represent two distinct circles or two rings, which are sometimes separated at a considerable distance from each other. It is found only at those parts where the different layers of the abdominal parietes are naturally liable to become separated. In the normal state it is usually occupied by vascular, nervous, or any other description of cords. Its track, which may be allowed to have walls, is caused by its two orifices being kept more or less widened by the muscles or other tissues, and by its two rings belonging to two different descriptions of aponeurosis. If its internal and external openings are exactly opposite to each other, the canal is straight or perpendicular. On the contrary, it is oblique when they are situated at an unequal distance from the median line. It is to be added, however, that hernias, provided they have existed ever so little time, have a tendency to obliterate the obliquity and canaliculated form of the openings under consideration, and to transform them all into simple rings by a process which is easily explained. The deep-seated and the superficial aponeurosis being pressed upon in an opposite direction by the portion of organs which has obtruded, and by that which still has a tendency to make its escape, gradually obliterate the interval which naturally separates them, and are ultimately found in contact. An oblique hernial canal, taken in its ensemble, is sufficiently well designated by the shape of an elongated Z. Now it is evident that the viscera which occupy a canal of this description, naturally tend constantly to straighten it by their own

weight, and to bring its two openings in face of each other, and that afterwards they may, as in the preceding case, conglomerate them into the condition of a ring, which is almost perpendicular. A hernial opening, however, whether it be a circle or a canal, almost constantly flares open in the manner of a funnel in the direction towards the abdomen, more so in some persons and less in others. As on the other hand, the vessels which are sometimes found in the neighborhood of the neck of the hernia are usually situated in the substance of the fascia propria, that is to say between the peritoneum and deep-seated aponeurosis, it results from this, that they are generally found pushed back to the distance of at least two or three lines from the fibrous border, which causes the strangulation, and upon which we are compelled to act with a bistoury in order to overcome the débridement.

## ARTICLE II.—RADICAL CURE OF HERNIA.

Whatever may be the seat of the hernia, it always forms an infirmity if not a disease sufficiently alarming to have urged persons at every epoch not only to seek a palliative for it, but also to effect its radical cure. The singular idea which induced the ancients to rank it among immoral diseases, a notion which is still so prevalent that country people frequently struggle in secret against the symptoms which it may give rise to before complaining of them to the physician, constituted an illusion which charlatanism naturally converted to its advantage. Hernia also has had, since the time of Hippocrates, Galen, and Celsus, as it also still has at the present day, pretended curers and *hernial* physicians who are exclusively occupied with the treatment of this disease. It would be unjust however to censure indiscriminately the numerous trials that have been undertaken to accomplish its radical cure, even since art has been in the possession of valuable means for retaining it. Laboring persons and workmen, who in general are most liable to it, derive but little advantage from palliative means. The most perfect bandages are far from procuring among them the beneficial results that are obtained from them in the elevated classes of society. The pelote almost always escapes from the abdominal ring at the expiration of a few days or weeks, and frequently the entire truss soon becomes nothing more than a new source of dangers.

### § I.—*Topical Applications, Compression, Position.*

The *emplastrum contra rupturam* of the ancients, the brick cerate (cérat de brique) of J. Fabricius, the vinegar bags of Verduc, the sandal wood, tormentil, turpentine, and topical applications of Baby-net and Mlle. Devaux, the famous remedy of the Prior of Cabrière, a remedy which consisted of an astringent plaster applied over the hernia, and muriatic acid given internally; the cataplasm of iron filings while diamond was administered internally, as recommended by A. Paré, after the advice of Guy de Chauliac; the decoction of dog-grass and spurge laurel, as used by Arnaud; the carbonate of ammonia mentioned by M. Belmas, and a thousand other remedies

of the same description, no longer find any advocates at the present day, except among quacks and old women.

## § II.

It is not altogether the same with *compression*, which has been successively lauded by Celsus, Theodorus, Aetius, G. de Salicet, Norsia, Blegny, Tre-court, J. L. Petit, Juville, &c. Steadily persevered in and applied in a proper manner, it has frequently effected a radical cure, without being under the necessity for this result of carrying it so far as to produce the gangrene which has been recommended by some in Germany. M. Fournier, M. Beaumont, and M. Duplat, have endeavored to bring it into repute among practitioners, while maintaining that if it is combined with astringents, it may cure almost every description of hernia.

## § III.
